CYLINDROMA OF THE ORBIT AND LIDS, WITH REPORT OF CASES.*

JOHN E. WEEKS, M.D.
NEW YORK.

The neoplasm to which the term cylindroma has been applied is characterized by the formation of hyaline cylinders, tubules, and lobulated masses, as a result of a degenerative process, the hyaline tissue composing a relatively large portion of the tumor. The term cylindroma was first employed by Billroth.[1] Henle termed this form of neoplasm syphonoma; Meckel, tubular enchondroma; Friederich, tubular sarcoma; Foester and Köster, mucous cancroid; O. Becker, adenoid der Thrauendruse; other synonyms are mixed tumors, angioma, myxo-adenoma carcinomatosum (Knapp), endosarcoma myxomatodes, carcinomatous cylindroma, endothelioma.

Ziegler,[2] writing of this growth, states that "either the cells form hyaline products or they themselves become converted into such or the fully developed connective tissue and the blood vessels undergo degeneration."

Hektoen and Riesman write as follows: "The stroma of some endotheliomas is subject to metamorphoses of various kinds. In a variety, usually originating from the endothelium of the blood vessels, a hyalin transformation of the vessel walls and of the stroma produces the growth called sarcomatous cylindroma.

According to Arndt,[3] not only do the cells of the adventitia, but also the cells of the interna take part in the hyaline degeneration of the blood vessels in these growths.

Virchow writes, "If a tumor springs from the cells of the blood vessels or lymph channels it is termed endothelioma."

The growths to which the term cylindroma has been applied occur most frequently in connection with the salivary gland.[4] They also form a large proportion of the tumors that are connected with the lachrymal gland. The hyaline changes may occur in rodent ulcer of the eyelid, and, according to Ziegler,[2] in simple sarcoma, endothelioma, and hemangiosarcoma.

The cases that have occurred in my practice are as follows:

Case 1.—Mary B., aged 32, married, mother of two healthy children, came to the New York Eye and Ear Infirmary Feb. 11, 1905. Ten or eleven months previously she noticed that there was something wrong with the left eye, but paid no particular attention to it until two and a half months ago when it began to be more prominent than the right eye. The protrusion of the left eye has gradually increased to the present time. There has never been any pain of moment, but there were occasional pricking sensations.

Status Præsens.—Patient well nourished; apparently in good health aside from the condition of the left eye. Left eye displaced downward, outward and forward (Fig. 1); so much so that forcible attempts to close the eye result in covering only about three-quarters of the cornea. Movements of globe limited in all directions, particularly above. Ocular and palpebral conjunctiva injected; lids slightly swollen. Iris reacts almost normally to the usual stimuli. Fundus slightly pale. Optic disc paler than its fellow. Arteries small. Veins dark, but not enlarged. Upper temporal vein tortuous. Vision 14/200. Field of vision normal in extent. On palpation a firm mass was felt which extended from the outer to within a few millimeters of the inner upper angle of the orbit, close to the margin of the orbit and apparently extending backward into the orbit. The anterior margin of the mass was about 1 cm. thick. There was no involvement of the frontal sinus or nasal cavity. The right eye was normal.

Operation.—Ether anesthesia. Incision along the supraorbital margin through the tissues to the periosteum. The orbital septum was exposed and divided close to the margin of the orbit. When this was done the margin of the tumor, dark purple in color, came into view. By blunt dissection the tumor, which possessed an irregular surface, was separated from the orbital tissue and from the orbital plate of the frontal bone. It was found that the levator palpebræ superioris muscle was involved in the tumor mass and that part of it had to be removed with the tumor. The lachrymal gland was also involved and was removed. The supraorbital branch of the fifth nerve was loosely connected with the thin capsule which enclosed the tumor and a portion of it was removed. In freeing the tumor, a projecting portion on its lower surface was broken through, but was recognized and dissected out so that the entire mass was removed. The hemorrhage was inconsiderable. The under surface of the orbital plate of the frontal bone was eroded, but there was apparently no communication with the cranial cavity or with the frontal sinus. The tumor extended two-thirds of the distance from the margin to the apex of the orbit. The cavity which lodged the tumor was thoroughly cleansed, shreds of tissue were removed, the orbital plate curetted and the wound closed. The margins of the orbital septum were united with catgut sutures, the integument with silk, and a dry dressing was applied. Kroelin's operation was not resorted to, as it was not found necessary.

Size of Tumor.—The antero-posterior diameter of the tumor was 1½ inches (33 mm.); transverse diameter, 1 5/16 inches (34 mm.); vertical diameter, 1 2/16 inches (30 mm.). Its superior surface was nearly quadrilateral; lateral and under surfaces very irregular.

Subsequent History.—Some traumatic swelling of the tissue of the lid and surrounding parts followed and lasted for a few days, but eventually entirely subsided. The eyeball gradually assumed its normal position. At the end of two weeks motility had returned and was only slightly limited above and below. Vision became 20/200 +. There was no diplopia. The fundus presented much the same appearance that obtained before the operation, except that the bloodcurrent in the veins became normal in color. The tortuosity disappeared.

About the middle of April the patient again appeared at the clinic, presenting a recurrence of the growth. As my term of service does not include the months from April to October, the patient passed into the hands of Dr. W. B. Marple, who performed exenteration of the orbit. The recurrence had apparently taken place from that portion of the orbital plate of the frontal bone which had become eroded by contact with the primary growth. The mass filled the upper part of the orbit, extending backward to the apex, but had not involved the globe. The growth was rather soft and friable. Healing progressed favorably. It is as yet too early to determine whether a second recurrence will take place.

Histologic Examination.—Primary growth: The mass is completely enveloped in a capsule which is fairly thick anteriorly and thin in other parts. The portion that was next to the orbital plate of the frontal bone was roughened, it included the periosteum. Remnants of the lachrymal gland somewhat indefinitely separated from the tumor proper by an imperfect capsule were found in the upper outer part of the mass. The tumor proper consists of a dense stroma which composes the greater part of the growth and collections of cells arranged in masses and in the form of tubules, which might be called the parenchyma. The stroma, which is densest at the periphery, is composed of rather large bundles of connective tissue fibers, presenting a few fixed cells on and in the bundles. Clefts between the bundles are as a rule small and contain a few young connective-tissue and apparent endothelial cells; that is, cells that may have been derived from the endothelium lymph-spaces. Many of the bundles of connective tissue have undergone hyaline degeneration. While the greater number took eosin well, many were stained faintly with eosin and also faintly with hematoxylin, probably indicating the presence of mucin.

Blood Vessels.—The blood vessels are not large, nor are they very numerous. All appear in the stroma of the tumor, none in the parenchyma. The vessels in the capsule have well-defined walls; those in the body of the tumor mass are without walls or are limited by a single layer of endothelial cells. The walls of the smaller vessels in many places are enormously thickened and have undergone hyaline degeneration, the lumen of the vessel being greatly reduced, the endothelial cells crowded together, and a thin column of blood occupying the axis of the canal. In a number of places there is a marked increase in the endothelial cells of the vessels, the transition of the endothelium of the vessels into cellular tubules being evident.

Lymph Channels.—The lymph spaces appear to be almost filled with cells having elongated, flattened nuclei. The walls are composed of broad hyaline bands which anastomose or coalesce These bands are not perfectly homogeneous, but many of them are nearly so. Nearly all show striæ, indicating a fibrillar origin.

Cells of the Stroma.—Small round cells, mononuclear and multinuclear, new-formed connective-tissue cells in different stages of development, endothelial cells, usually in small groups.

Connective Tissue.—Arranged in large bundles and massed together, particularly at the periphery. Nearer the center and where the cells of the parenchyma are not plentiful, the connective tissue is less dense and forms trabeculæ. In the recurrent growth the parenchyma predominates over the stroma.

Elastic Connective Tissue.—Sections of the primary and of the secondary tumors stained with Weigert's elastic-tissue stain show numerous elastic-tissue fibers intermingled with the non-elastic-tissue fibers, proportionally more plentiful in the connective tissue septa, which go to form irregular alveoli in which the cells of the parenchyma are lodged.

Recognizable Tissue of the Lachrymal Gland.—Occupying the upper outer portion of the tumor is a small, thin plaque of tissue which contains the remnant of the lachrymal gland. This consists of a number of acini, more or less distorted and separated one from the other by a stroma rich in new-formed cells. The acini are irregular in shape, the cells of the acini arranged in a single layer, often with large lumina the protoplasm of the cells seemingly small in amount, the cells cuboid in shape; frequently with small lumina, the cells apparently being more columnar in shape or more closely crowded together. In some parts the acini were much distorted, the lumina being long and narrow instead of circular, as in the normal acinus. Wherever an aggregation of cells suggesting acini was found, lumina were present, apparently limited by a fenestrated membrane as described by Verhoeff.[5] The acini and the cells of the character forming acini appeared to be separated from the main growth by a more or less definite connective tissue wall of some thickness, a condition that has been pointed out by Veasey[6] and others.

Parenchyma.—The cells which form the parenchyma of the tumor proper are large, slightly oval or cuboidal, seldom columnar. They are arranged in irregular masses, often in tubular masses, with a fairly sharply-defined limit. The cells fill the entire space between the walls of the stroma, no lumina being present. The masses of cells contain some leucocytes. Not infrequently a degenerated area marked by faintly-staining fragments of cells, granular substance and irregular hyaline masses is seen. Many of the cells composing the masses just described closely resemble the cells which are found in ordinary endotheliomata. Many might be modified epithelial cells so far as their morphology is concerned. There is apparently no positive evidence regarding the true origin of these cells. The spiral fibers of Herxheimer,[7] which he regards as peculiar to stratified, tesselated epithelium, could not be demonstrated. A limiting fenestrated membrane indicating glandular lumina was absent.

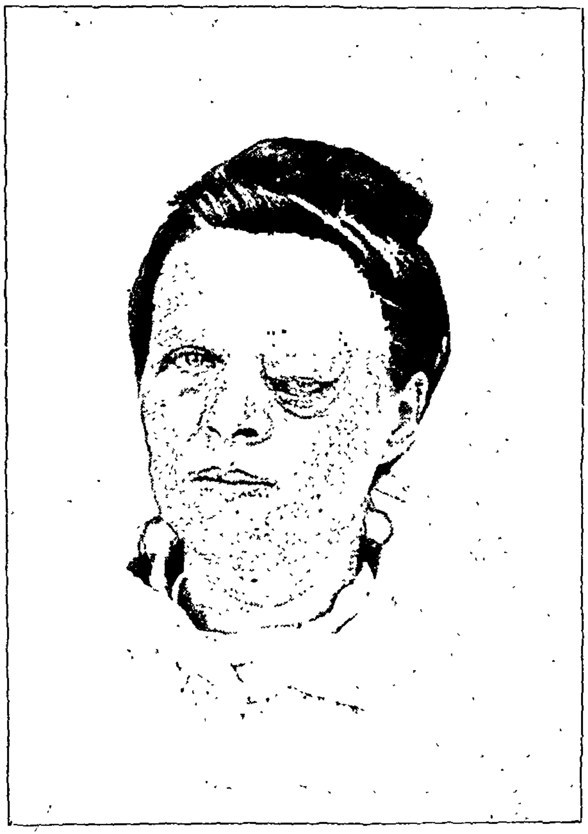

Fig. 1.—Cylindroma of the orbit.

The recurrent tumor resembles the primary tumor except that the cells of the parenchyma are much more numerous, forming the bulk of the mass, and that the hyaline degeneration was not so conspicuous.

Case 2.—Mr. S., aged 46 years, came to the New York Eye and Ear Infirmary in May, 1891, suffering from an ulcer of the right lower lid, situated 3 mm. below the margin of the lid and measuring 5 mm. in its vertical and 8 mm. in its horizontal axis. The margins were slightly raised, thickened, and irregular. The ulcer was shallow, the floor being covered by a grayish secretion and crusts. The ulcer had commenced some years ago as a small elevation with a scaly apex. There was very little irritation. After a time the roughened, thickened epithelium gave place to a small ulcer and a scab. The ulcer slowly increased in size in spite of treatment.

[7] Monatschr. f. prakt. Dermatol., xi, p. 89.

Operation.—A diagnosis of epithelioma was made and the growth was excised. The recovery was rapid. The patient was discharged and was lost sight of.

Microscopic Examination.—The growth consisted of epithelial digitations which dipped into the tissue from the surface, and margin of the ulcer. The periphery of the growth was composed largely of hyaline bands or tubules which had apparently developed because of changes in the endothelium and adventitia of small blood vessels and of lymph channels. The tissues resembled closely the hyaline tissue that was present in the growth in the case first described.

GENERAL NATURE OF THE ORBITAL GROWTHS WITH HYALINE DEGENERATION.

Aside from the characteristics just described, tumors of the orbit of this nature sometimes develop myxomatous tissue, cartilage and true bone. These are products of mesoblastic tissue and stamp the growth certainly, so far as the stroma is concerned, as mesoblastic in origin. If the cells of the parenchyma are of endothelial origin, the term endothelioma to designate this feature followed by the term cylindroma to denote the peculiar hyaline structure, would be appropriate. The lachrymal gland does not always accompany the growth that results in the formation of cylindromatous tissue; however, I have been unable to find any reports of a case from which epithelial tissue could be entirely eliminated. It is possible, as held by some observers, that the parenchyma of these growths is largely of epithelial origin. The morphology of many of the cells does not contraindicate this supposition. Ziegler writes, "I have classified as endothelioma those tumors . . . which are characterized by the formation of cell cords in the lymph channels on the assumption that these cords of cells arise from endothelium of the lymph spaces and lymph vessels. I must admit, however, that I do not consider this assumption as absolutely proved."

Taking into consideraton the fact that these tumors contain hyperplastic tissue which develops largely from mesoblastic tissue, but that epiblastic tissue is always present and may preponderate, it is evident that the tumors are "mixed tumors." However, since the peculiar hyaline change that takes place in mesoblastic formations in these growths is often so striking a feature, I believe with Verhoeff that the term cylindroma should be retained.

MALIGNANCY.

In regard to recurrences after the removal of tumors of this character from the orbit I am convinced that the reports of cases are misleading in this respect, as they are often made too early to determine whether a recurrence will or will not take place.

Of 56 cases cited by Lagrange[8] recurrences were mentioned in 11. Of 26 other cases, the reports of which I have reviewed, recurrence took place in 8.

In a case observed by Ewetsky[9] metastasis took place in the liver, resulting in the death of the patient.

The reports of these cases lead one to conclude that they are not so malignant as ordinary sarcoma and carcinoma, but they require most thorough removal. If osseous structures are involved, they should also be removed. Metastases occur very rarely. Tumors of the kind described have been observed in individuals from the age of 17 to 72 years. A number have developed after traumatism.

Association of lachrymal and parotid neoplasms has been noted by de Wecker and Masselon[10] and others.

DISCUSSION.

Dr. C. R. Holmes, *Cincinnati*, reported the case of a patient with the history of painless displacement of the left eye, vision normal. At the upper inner canthus one could feel a mass, hard, yet somewhat elastic. On making an inverted T-shaped incision at the upper inner angle of the orbit, Dr. Holmes found that the mass was not a distinct tumor, but that the partially broken down os planum had been pushed into the orbit. Opening it, he found several small nodular masses extending into the ethmoid cells. He removed everything back to the sphenoid and up to the cribriform plate, and did not sew the wound up entirely, but left space for drainage. The wound gradually contracted and finally closed entirely. Two pathologists who examined specimens could not give a positive diagnosis. Dr. Weeks pronounced it an endothelio-cylindroma. To make sure that syphilis played no part in the case and before Dr. Weeks' assurance of the diagnosis was received, the patient had been given a thorough course of antisyphilitic treatment, which, however, made no impression on the local conditions. Dr. Holmes said that the history of the case warranted him in eliminating this factor. Two weeks ago patient was well, but with slight displacement of globe. Vision and ophthalmoscopic examination were then negative.

Dr. E. V. L. Brown, Chicago, referred to the paper read in the Section on Pathology and Physiology by Dr. Zeit, who laid especial emphasis on the tendency to hyaline and mucoid degeneration and the frequent recurrence, but infrequent metastasis. He looked on these tumors as sarcomata of slow growth, as exemplified in Dr. Weeks' case.

Dr. John E. Weeks said that he thought that these tumors constitute the majority of the tumors of the orbit that originate in the lachrymal gland. Such tumors are not numerous, but they form a relatively large percentage of the tumors of the orbit; consequently their study is of great importance.

DIFFERENTIAL DIAGNOSIS OF INTRAORBITAL TUMORS.*

FLAVEL B. TIFFANY, A.M., M.D.
Professor of Ophthalmology, U. M. C.
KANSAS CITY, MO.

That the subject of differential diagnosis of intraorbital tumors is worthy of consideration is emphasized by the egregious mistake made recently by some of the members of the Association in the case here reported. My object is not to criticise those who saw, examined and made their diagnoses, but rather to emphasize the liability even of eminent oculists to err in their diagnoses of growths of the orbit and consequently to advise treatment which if carried out would be damaging to the patient as well as to the oculist.

Before proceeding to administer treatment for intraorbital tumors, we should arrive, if possible, at a correct diagnosis, as there are several kinds of growths which invade the orbit, and not all are amenable to the same treatment. Among the several kinds of growths of the orbit there exist both benign and malignant. There are bony, fleshy, bloody, nervous, fatty and serous tumors. Among the benign are the lipomatous, fibrous, cystic and osseous. Among the malignant, are carcinoma, sarcoma, epithelioma, glioma, and polypi. The benign may have their origin within or without the orbital walls, but most of them grow from the periosteum of the orbit, or from within the cone of the recti muscles. On the other hand, nearly all, if not all, malignant tumors of the orbit originate from within the eyeball, or from some one of the neighboring sinuses opening into the orbit. Some come from the brain. Carcinoma, sarcoma and glioma, as a rule, start from within the eyeball. The fluid or semifluid tumors arise as a rule from the frontal sinuses or from the ethmoid

cells and contain pus or nuclei. The solid or gelatinous arise from the maxillary, sphenoid or ethmoid. From these latter almost invariably there is scotomata and occasionally there is complete blindness from optic neuritis or atrophy of the optic nerve. Epithelioma comes from the lachrymal duct or canal; polypoids, from the antrum of Highmore; cystic tumors from the frontal sinuses. Osseous tumors more frequently arise from the periosteum of the supraorbital plate, occasionally they spring from the inferior wall. Vascular tumors, such as angiomas, nevi and some of the aneurisms as a rule, come from the intracranial cavity. Most orbital aneurisms arise from the orbital branch of the ophthalmic artery where the latter leaves the internal *carotid*.

DIFFERENTIAL DIAGNOSIS OF ORBITAL TUMORS.

Of course this can not always be done, as has been demonstrated in the following case, but, as a rule, with a definite knowledge of the symptoms of these various growths and a careful examination, one can be pretty certain of the real nature of the growth. Malignant tumors run a rapid course and sooner or later produce pain, ranging from a slight ache to a most agonizing distress, and if they are allowed to run their course they destroy vision and attain enormous dimensions, pushing the eye out of the socket and extending far beyond the limits of the orbital cavity.

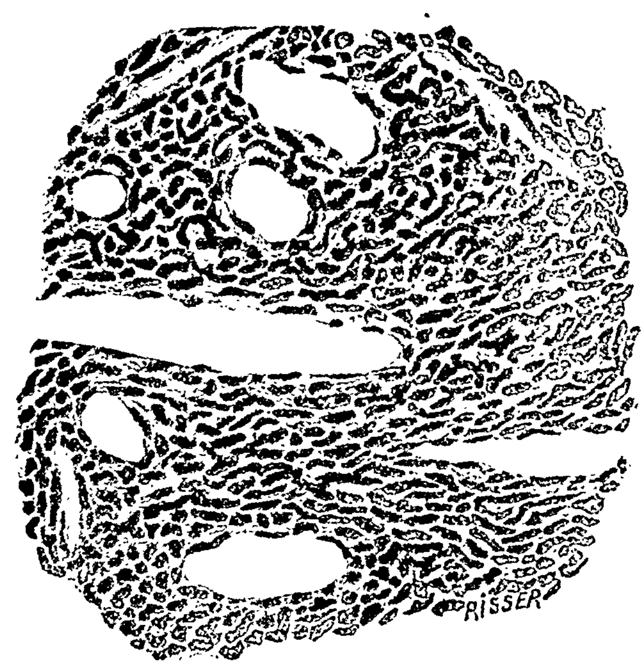

Fig. 10.—One-fifth objective.

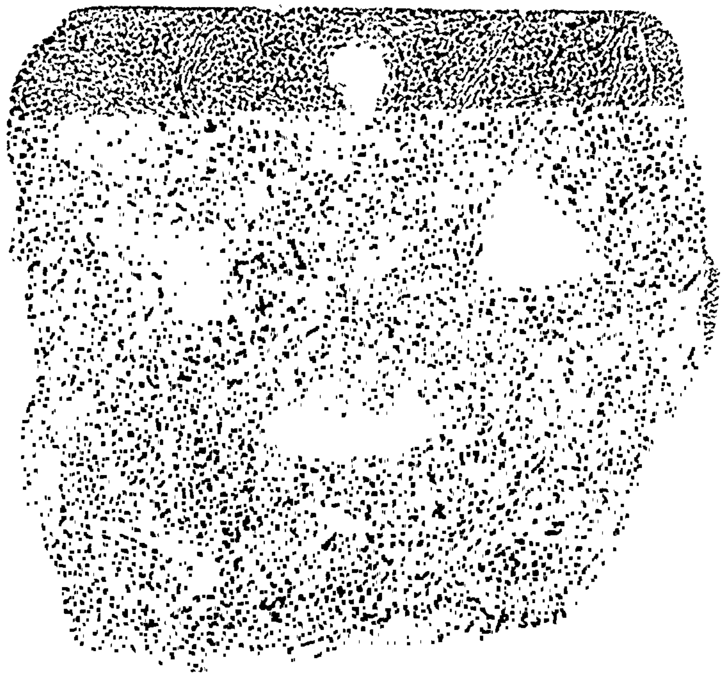

Fig. 11.—Two-thirds objective.

On the other hand, benign tumors grow slowly, they may exist many years before attaining any considerable size, they rarely give pain, nor do they as a rule destroy the vision. By pressure on the optic nerve, however, they may produce neuritis or neuroretinitis and finally atrophy of the optic nerve. There is always one symptom common to all forms, excepting a luxated lachrymal gland, namely, proptosis. This exophthalmia takes different directions, and this locates the seat of the tumor. If the tumor is at the apex of the orbit or within the cone of the recti muscles, the extruded eye will take the direction of the orbital axis; if the eye is pushed outward and downward, it indicates the seat of the tumor as being at the upward and inward portion; if the eye is pushed inward and downward it indicates the location of the tumor as being upward and outward. With the little finger, one can get behind the eyeball, and if on palpation the tumor is found to be hard and immobile, we can conclude that it is of an osseous nature, especially if the tumor be of slow development. If the tumor is soft and fluctuation can be detected, it may be of a serous, phlegmonic or sanguinous nature. If it is soft or yielding without fluctuation or pulsation it may be fatty, as a lipoma; or if soft and less yielding without fluctuation it may be fibroid or glandular, as an adenoma. If it is vascular, as an angioma, nevus or aneurism, there will exist pulsation and bruit, especially if the patient takes the stooping position with the head hanging low. Osseous tumors do not change position or size in any change of position of the patient; to a certain extent, however, this is true of all tumors of the orbit with the exception of the sanguinous. In fatty and fibrous growths pressure on the tumor may cause more proptosis of the eyeball; but on the other hand pressure on the eyeball will probably cause more prominence of the tumor. In pulsating tumors, the upper lid is swollen and tense, especially are the veins hyperemic, with an elevation of temperature, both lids frequently being everted. The protruding lids and exophthalmia being replaced will immediately return on removal of pressure. There is a continuous soughing or murmuring; sometimes the sound is of a whistling nature. Pressure on the carotid will cause the pulsation and noises to cease. The ophthalmoscope often reveals a papillitis or atrophy of the optic nerve. Venous pulsation is nearly always present and not infrequently arterial at the margin of the optic disc. Patients with angioma complain of a knocking, roaring or buzzing in the head and ears. This disease is more frequently seen in women than in men. It is difficult to determine the different varieties of pulsating tumors. The vascular are more resistant than aneurisms and their position, as a rule, is out of the line of the axis of the orbit. The pulsating tumor is usually found at the inner and upper part of the orbit and the bruit is of a continuous murmur and is complicated with a vesicular murmur of each systolic action of the heart. There is frequently a paresis of some of the nerves of the eye muscles, ptosis occasionally existing. In pulsating malignant tumors ligation of the common carotid does no good. In angioma, in all cavernous tumors and in aneurisms, on making pressure on the tumor or eyeball there will be a recession of both eyeball and tumor; or, if the patient takes the horizontal position the eye will settle back into the orbit. The principal diagnostic symptom of an angioma or aneurism, however, is the bruit heard by means of the stethoscope together with the pulsation felt by palpation.

REPORT OF A CASE.

The following is a letter received previous to the arrival of the patient:

Dr. Flavel B. Tiffany. Dec. 2, 1904.

Dear Doctor:—I have patient who has been to all the eye men in the western country. His case has been variously diagnosed. Some call it angioma, others aneurism, and one man has diagnosed enlargement of the lachrymal gland. His condition is rapidly getting worse and something must be done soon. The growth is situated behind the eyeball, pushing the latter out to an enormous degree. It is a pulsatile tumor, not painful. The only pain is caused by the accompanying conjunctivitis, which is caused by failure of approximation of the lids. The patient is poor, but very worthy, and his case is one which I am sure would prove very interesting to your class. I would like to have him consult you if you could do it charitably; then if there is any operative work to be done he might be able to pay you something. If you can do anything, would some day next week suit you? Hoping to hear from you soon and trusting that something can be done for the poor fellow, I am, truly, Ralph L. Funk.

The patient consulted me first December 10, 1904. I give the history in his own language:

History.—I am 38 years old, married, and by birth a German. I am a farmer and live at Baker, Kansas. Five years ago my wife first noticed something wrong with my eye. I did not notice it until we had a picture taken of the family group, when I saw that my left eye bulged. I went to the family doctor several times, but he did not seem to know very much about it. I then went to Dr. R., who took out a piece about as big as the end of my thumb. My brother said that the substance was stringy and that he removed it with a hook. Two days after the operation the doctor told me that he had not gone deep enough and would have to operate again, but the chances were that I would lose the sight of my eye. I had lost confidence in him, so I went to St. Joseph to see Dr. W. He described the case to me and told me that it was a bad case of bloody tumor. He used the electric needle five days to clot the tumor, as he said, and then he would pick it out. He said I should have to take chloroform. My brother witnessed the operation, and he said I had a severe hemorrhage and Dr. W. told me that I lost three and a half pounds of blood; he said that he stopped the flow with hot irons. Six weeks after this operation I went back and he wanted me to let him take the eye out and get at the root, but I was afraid. I then went to Dr. B. of Nebraska, and I was in the chair ready for the operation and the assistant ready to give the chloroform, when the doctor, after making a more careful examination, said that if I would rather, he would present the case before the Academy of Ophthalmologists and Otologists at Denver, Colo. Said that the celebrated eye doctors of America were having their meeting at this time at Denver. I went before them and they decided it was angioma. I then had an opportunity to go to Omaha and while there I consulted another eminent oculist, but he could not tell what the trouble was and said if I was in no hurry he would write to Dr. Knapp of New York, who had a case like mine twenty years ago when he was a student of Dr. Knapp's, and the operation was successful. He was to let me know when to come up for the operation, but I have never heard from him. I then went to Dr. Funk, whom I have known for some time, and he advised me to consult you. I have never had any serious sickness nor injury on the head that I can recall. I had la grippe about one year previous to noticing anything wrong with the eye.

A day or two after giving the history the patient received the following letter:

Dec. 14, 1904.

Dear Sir:—Since you left I have looked up the matter of tumors similar to yours and believe that it would be better to try tying the internal carotid artery to see if that will not stop the progress of the disease without operating on the orbit directly. If none of the surgeons there care to do this for you, you can have it done here, or if this does not cure you it will then be time to consider a direct operation on the orbit.

Yours sincerely, ———.

Before operating, I presented the case to our local society, the "Academy of Medicine," and after getting the history from the patient and examining him it was the consensus of opinion that the tumor was an angioma; several declaring that they detected pulsation and bruit; one oculist advised enucleation of the eyeball and extirpation of the tumor. I did not agree with them, as I could not detect the least pulsation, nor could I hear any bruit, nor would the eye or tumor change position with the changing of position of the patient. I said, however, that an operation would tell and we would be ready to stop all hemorrhage. I asked Prof. Jabez N. Jackson to assist and to be ready, if necessary, to ligate the internal carotid artery.

Examination.—The eye was displaced downward and inward, locating the position of the tumor, viz., upward and outward (Figs. 1 and 2). There was little if any change of position or size of the tumor when the patient was in a stooping posture with the head hanging low, or when he was standing or lying in the horizontal; nor could we change the size of the tumor by pressure, all of which went to show at least that it was not an aneurism and to a certain degree not an angioma. The lids showed some venous hyperemia as Figs. 1 and 2 indicate. This I attributed to meddlesome surgery, for, according to the patient's statement, he had had several operations, which with the normally high vascularity of this region would be likely to produce hyperemia. From the history as given by the patient particularly, if we may rely on what he said in regard to the opinions of the physicians whom he had employed, more especially the opinion of the members of the society of oculists who saw him at Denver, as well as the letters received, without due consideration and careful examination I might have jumped at the conclusion that it was a case of angioma; but with careful examination with the stethoscope no bruit was heard and by palpation not the least pulsation was detected, not even with the head hanging low. I was inclined, therefore, to discredit any existing angioma or aneurism, especially as this growth was only of five years' standing, coming on after middle life and without history of an injury. The ophthalmoscope showed no arterial nor venous pulsation at the disc, although the latter was somewhat blanched, this being due, probably, to the pressure of the tumor. There was some hypermetropia, caused also by pressure shortening the antero-posterior axis, but there was no hemorrhage nor scotoma. The tumor was evidently not malignant, as it was of slow growth and had given no pain and had not destroyed the vision. It was evidently benign in nature and did not come from any of the neighboring sinuses; nor was it osseous, for it was movable. By exclusion, therefore, it was logically concluded that it must be one of three kinds: fibroma, lipoma or adenoma. I have had two cases of luxated lachrymal gland in my experience, but the gland being so high in the orbit did not displace the eyeball much, so I was inclined to think that this was a fibroma or a lipoma.

Technic of the Operation.—December 22 I performed the following operation: I first passed a black suture through the external rectus for sake of identification. I tenotomized this muscle in order better to liberate the tumor from the muscles. I then made an extensive canthotomy, cutting through the orbicularis. At the margin of the orbit I went in back of the conjunctiva, taking care not to disturb more than necessary any of the extrinsic ocular muscles, nor the levator palpebræ superioris; then, by traction, I tore the tumor from its mooring, which was somewhat adherent to the recti muscles. There was some hemorrhage, but there was no trouble in controlling it with the hemostats. I finally detached the tumor in its entirety.

In incising it, the pathologist pronounced it an adenoma, thinking it to be the lachrymal gland luxated from its bed in a hyperplastic condition, having increased in size and weight. The dimensions of the tumor taken by the calipers were 28 mm. horizontally, 38 mm. vertically, and 22 mm. transversely. Its weight was 19.5 grams. Figures 1 and 2 show the appearance two days before the operation, and Figure 6, ten days after the operation; Figures 3 and 4 show the bulk and shape of the tumor, the illustration being natural size. Figure 5 shows the tumor cut open. A photograph taken four days after the operation (Fig. 7) shows the swelling of the lids not all gone, with complete ptosis and ankylosis of the eyeball, but it has receded into the orbit, and the vision is even better than before the operation. There is a decided convergence of the eye with ankylosis, indicating a paralysis of all the extrinsic ocular muscles except the internal rectus, but these conditions gradually improved as the swelling subsided. A photograph taken two weeks after the operation (Fig. 8) shows the swelling of the lids and the chemosis of the conjunctiva nearly gone and the eyeball receded into the orbit. There is complete paralysis of the levator palpebræ superioris and of all the extrinsic ocular muscles, the patient not being able to lift the lid nor to move the eyeball in any direction. The tearing of the tumor loose from its attachment evidently disturbed the nerves innervating these muscles, besides there has been some intraorbital cellulitis, which accounts for the ankylosis. The patient says that the whole left temporal and supraorbital region half way back is numb and void of all feeling, but the paralysis and anesthesia were transitory and in time passed away. He handed me several photographs taken at different periods of time for the past sixteen or eighteen years. These pictures establish the fact beyond doubt that the tumor did not start until about five years ago, and that it was of slow growth.

The special thing this case teaches us is not to depend too much on the history of the case from a layman's point of view, but to examine closely and to arrive if possible at a correct diagnosis before outlining the treatment.

I was inclined to rest content and to agree with my colleague, and to call the tumor a dislodged lachrymal gland until I submitted it to our pathologists, one of whom called it a fibrosarcoma, and the other an angiomyoma. After this controversy, the tumor was sent to Chicago. Dr. Emil Ries and Dr. Zeit pronounced it an endothelioma or a perithelioma.

This patient last called on me June 1, 1905, and there was no evidence of the tumor returning either locally or metastatically. The muscles had regained in part their function. His vision is now sufficient to read newspaper print. Figure 9 shows the appearance of the eye at this time.

Microscopic examination showed principally that the blood vessels had no definite walls. (Figs. 10 and 11.)

Patent Medicines in Norway.—It is reported that a new law in Norway forbids the newspapers to publish advertisements or in any way to further the sale of any and all foreign patent medicines.

ONE OF THE CAUSES OF IMPERFECTION IN THE RADIOGRAPHIC IMAGE.*

HENRY POWER, M.D.

SPOKANE, WASH.

Two recent articles on the *x*-ray in THE JOURNAL of the American Medical Association have interested me much. One in particular, in which the author, Dr. Stover of Denver, touches on the subject of the formation of *x*-rays at parts of the Crookes tube remote from the target. The belief in the formation of such rays is widespread and, no doubt, has some origin in fact. I wish in this paper to show that in some cases at least these rays are not thus produced, and can not, therefore, be held responsible for the bad effects noticed in radiography which are usually laid at their door. That there is, nevertheless, some obscure cause at work which tends to reduce the sharpness of the radiograph or of the fluoroscopic image is undoubted and it may be stated further that the *x*-rays do reach the photographic plate from directions other than that in which the target of the tube lies. In order to demonstrate the true origin of these interfering rays, I have performed three experiments, the results of two of which appear in the illustrations. The reproduction shown in Figure 1 is taken from a negative in which different parts of the plate were treated in three different ways. The part marked A was used to receive an exposure of the metacarpal bones in the ordinary manner. The part faintly showing the fingers of the hand, marked B, was exposed at the same time, but a sheet of lead 1/16 of an inch thick was suspended between the target and the hand exposed and at a distance of twelve inches from the hand and plate. Over the two narrow strips marked C, strips of lead were placed having the same thickness as the first, but in apposition to the plate. It will be noted in this illustration that the shadow C is much more dense than the shadow B, though the lead in each case was 1/16 inch thick. To account for this difference, we must assume that the rays which produced the image seen at B must have passed around the edge of the lead and not through it.

If they passed around the edge, we may assume three possible methods by which they accomplished their results:

1. They may have come from a different source of light in the tube, accessory rays. 2. They may have bent from their normal straight line, refracted rays. 3. They may have been produced by the action of the well-known rays from the target, striking the air and causing it to give off new rays in new directions, induced rays.

I am unable at present to devise an experiment which will distinguish between refracted and induced rays, but in regard to the first form, the accessory rays, that they, on this occasion, do not exist, is proved by the following experiment made with the same tube, coil, etc.

A completely closed lead box, which may be considered as a photograph camera for *x*-ray work, was placed fifteen inches below the target of the tube. The camera itself being five inches deep, with the photograph plate at the bottom, it will readily be seen that the plate was twenty inches from the target. As is well known, it would be impossible to use a lens by means of which to form an image of the source of *x*-rays in the tube, so that for this purpose resort was had to what is known as pin-hole photography. In other words, the front of the camera was pierced with a minute round hole, which would allow the x-rays to pass through and which at the same time was so small that they would be forced to form an image on the plate at the botttom of the camera. The plate was now prepared in the ordinary way for x-ray work by enclosing it within two light-tight paper envelopes, and then placed at the bottom of the camera. The x-ray was now turned on and a long exposure given. In examining the resulting negative, it is noted that it is perfectly blank with the exception of one spot (Fig. 3). When one examines this spot one sees that it represents a picture or image of the target of the tube, and, on measuring it exactly, I find that its diameters are exactly one-third of the diameters of the target. In the center of this spot there is a far more dense spot, having a slightly oval shape, and the diameter of about 1/8 of an inch. This dense spot represents an image of the active central part of the target, where the cathode rays come to a focus; this measurement multiplied by three gives the diameter of the focus as about 3/8 of an inch. Over all the rest of the plate no effect has been produced by the action of the rays, though the various parts of the plate must have been exposed respectively to the effect of any x-rays which emanated from the various parts of the tube other than the target. I feel that this negative, therefore, proves that in this particular instance, at least, no x-rays worthy of notice were produced in any art of the tube, with the exception of the target. In the illustration the faint image of the target has been lost and only the image of the central or focus point is shown.

---

* These experiments were performed in February and March, 1905; the paper was read at the April meeting of the Spokane County Medical Society.

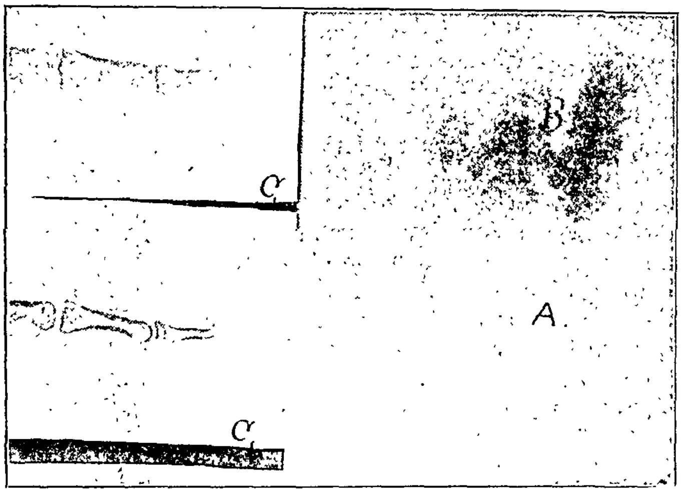

Fig. 1.—Printed lightly to show the image of the fingers produced by the lawless rays which have been induced by the lawful rays which affected the plate at A.

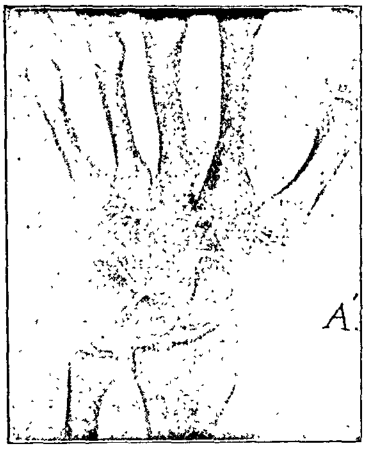

Fig. 2.—Print fully exposed from part A of negative from which Fig. 1 was taken.

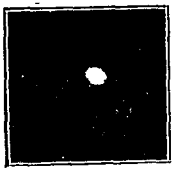

Fig. 3.—An image of the source of x-rays in an active tube taken by pinhole photography with a lead camera and a plate protected from ordinary light.

I am therefore forced to the conclusion that the rays which caused the trouble in this work, as illustrated at B in Figure 1, are produced in one of the two other ways, and probably by the regular rays inducing new rays by their effect on the air through which they pass.

OPERATION FOR CANCER OF THE MOUTH.*

W. W. GRANT, M.D.
DENVER.

The advantages claimed for the new operation which I have recommended[1] for carcinoma of the lip are: a better, more useful mouth, and, with less tension, a fuller and more natural lip and expression. There is also the distinct esthetic advantage that the lines of incision are less conspicuous, and in men, the usual victims of carcinoma, are soon covered entirely by beard. Plastic surgery means the free use of the knife in liberal incisions, and infinite patience and attention to details. In some respects this is more important in the surgery of the face than of any other part of the body. I know of no department of surgery which taxes more severely the skill, nice sense of proportion, harmony and delicate technic of the surgeon. In the unusually bad cases I report, the operation is tedious, bloody, of rather extensive proportions, and formidable in appearance during its progress; but results justify every step and effort in its consummation. The disease usually occurs in the lower lip of males. The operation is equally applicable to the upper lip, and to partial or complete excision of the lip.

The ordinary V operation, in common use so long that it seems heterodox to question its standing, is most inappropriate, except in small growths, with large mouths. Though the lips are very elastic, they can not stand the excision of the vermilion border with its broad base and apex on the chin. The sucker mouth results, and the tension and contraction are too great to make a useful mouth or a desirable appearance.

METHOD.

The method of procedure consists of two perpendicular incisions on each side of the growth, connected by a straight transverse incision at the base, which is usually about the crease between chin and lip. This leaves a quadrangular space to be filled by flaps. An incision is now made from each inferior angle of the wound, obliquely downward and backward beneath the maxilla, on a line about equidistant between its angle and apex of chin or symphysis. Its further extension is measured by the extent of lip removed and the glandular involvement. All the submaxillary glands are removed through these incisions except the submental, which may necessitate a separate incision in the middle line. When the lip is extensively involved, the cheek is completely separated from the inferior maxilla to the middle of the masseter muscle. After the glands are cleaned out the triangular flaps are brought together and united first in the middle line. If the tension is great or considerable, from the amount of tissue excised, I am in the habit of inserting one mattress suture about three-quarters of an inch from the central line and tying it over pads of gauze, covered with oiled muslin to prevent soiling. This effectively removes undue tension from the sutures in the center of the flaps. The stitches uniting cheek posteriorly are now inserted, or if previously inserted are tied, care being taken to include entire thickness of cheek or upper border. I use for this purpose interrupted silkworm gut or running stitch of chromicized catgut. A small rubber tube should be inserted in the posterior angle of wound on each side to drain the mouth and for irrigation purposes.

---

* Read in the Section on Surgery and Anatomy of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

[1] Medical Record, March, 1899.

The stationary chin tissue is of the greatest importance as a point of fixation for the flaps. In uniting the flaps to the chin, in the centers it is well to omit a stitch for drainage of the space between incisors and flaps. When half or more of the entire lip is removed, I am in the habit of perfecting and completing the operation by making an incision from each angle of the mouth backward and slightly downward half to one inch in length, down to the buccal mucous membrane, and then separating the latter from overlying tissues above, below and posteriorly to the extent of half an inch. The lip above and below is now beveled from the inner border in order to conform to natural conditions and also to make it easier to cover. The mucous membrane is now divided in the middle line and the flaps united to the skin by one continuous suture of chromicized catgut.

The orbicularis being cut in this part of the operation, the levator angulæ and superioris muscles will tilt or crimp the upper lip for two or three months at upper angles of the mouth. This is not a serious matter, as it will accommodate itself to the parts by the action of the depressors, and will hardly be noticed, if at all. Still, I am in the habit of cutting away more tissue at this point in order to limit this temporary defect. The operation is now complete in every detail, without leaving a single place to heal by granulation, or to be covered by future plastic work. The operation is completed with the application of gauze and bandage to face and head.

The ordinary method of anesthesia is objectionable in these operations, because in the way of the operator, causing much delay. To obviate this I have devised, and had made, a double nozzle on a single stem, which is attached to a Junkers inhaler in place of the ordinary shield. By this device the anesthetic, usually chloroform, is administered through the nose entirely, while the apparatus and anesthetizer are both out of the surgeon's way and the operation proceeds without interruption. The mouth is also filled, moderately, with gauze, and the swallowing of blood is prevented.

POSTOPERATIVE TREATMENT.

This is of great importance. There is no such thing as perfect aseptic surgery of the mouth. This applies with great force to dirty, extensive carcinomas with usually bad teeth and constantly infected secretions. Consequently, daily change of dressings is necessary, with irrigation of mouth, directly and through tubes, with mild antiseptic solutions, such as boric acid and peroxid of hydrogen. This is continued a week or more as the conditions may require.

The patient is fed in the meantime with milk and soups through a tube attached to a fountain bottle or the nozzle of an invalid mug. Salines are given in the same way when needed.

COMPARISON.

Excepting the V operation, those in most general use are the Langenbeck, Bruns and Diffenbach, with slight modifications. By Langenbeck's method the growth is removed by an elliptic incision, and the flap for the lip is taken chiefly from the chin on one side, leaving a spur from the opposite to stitch to.

Esmarch, Kowalzic and Volkmann perform the same operation, except in making a double flap, which leaves them without a stable attachment. Both are very objectionable in not having a mucous covering for the flaps, or vermilion border. The result is a contracted mouth and inverted lower lip. Furthermore, this hard, thin, bearded tissue is not the most suitable for the construction of a new mouth.

Bruns takes the flaps from the cheeks by incisions from the corners of the mouth. The flaps are brought down and stitched in position for the lower lip. The flaps would have to be retrenched to get mucous covering for the border of the lip. The denuded cheek surfaces are covered by immediate stitching, which leaves two conspicuous vertical cicatrices and necessarily constriction of the tissues below the malar eminences. These are objectionable features.

Diffenbach excises the growth by a V incision and then makes a straight incision from the corner of the mouth nearly to the tragus, then a downward incision beneath the maxillary line, dividing all the tissues, including the mucous membrane. The entire flap is then slided to the middle line and stitched, while the gap in the side of the face is immediately sutured, leaving conspicuous scars, and doubtless a salivary fistula, as Steno's duct is cut. Syme, Buchanan, and Sedillot take flaps from chin and side of face. The method I present is, I believe, the least objectionable of any yet devised. It is the only one, except Dowd's, which permits the extirpation of the glands, through the same incisions, for the formation of the flaps. It has always the advantage of flaps, already fully covered by mucous membrane, and a vermilion border easily and promptly covered by membrane and not taken from the flaps. No denuded surface is left for stitching or granulation. The tension of the lip is slight or negative, especially after a few months. The lip is more prominent and mobile and the mouth more natural in expression.

Finally, there is not a cicatrix beyond the angles of the mouth above the inferior maxillary line in the operation on the lower lip, and the existing ones are soon covered by beard, while use soon erases the wrinkles due to them.

I commend the operation to your most favorable consideration, no matter how little or how much of the lip may be involved, and at any stage of the existence of the disease, while in all cheiloplastic work, regardless of the cause, it is an addition to the surgeon's resources.

CASE 1.—Mary R., aged 13, had a severe attack of diphtheria a few years ago in the mountains of Colorado, which resulted in extensive sloughing of throat and mouth. This resulted in solid adhesion of the lips in their entire depth, except a small opening in the center. I operated Aug. 20, 1901, by excising the linear scar to the mucous membrane, then separating the latter for a third of an inch above and below, divided it in the center and stitched the flaps to the skin as in excision of the lip.

Case 2.—W. H. E., a painter, aged 64. Carcinoma lower lip, *extensively involving chin and glands beneath the maxilla,* as shown in photograph. Duration two years. Six months previous to the operation treated with *x*-ray by Dr. Stover of Denver. He had not talked without great difficulty for eight or ten months. Operation April 9, 1904. This was the most elaborate, the most difficult, and one of the bloodiest I ever performed or witnessed. The principle and method were as described, but in such an aggravated case, varied to meet the conditions presented. I made a straight perpendicular incision from the right angle of the mouth to a point well beneath the growth. As the left angle was involved, I first made a slight lateral incision and then a perpendicular one parallel to the former, connecting both by a straight transverse incision, completing the excision by dissecting the tumor from the chin, leaving a large quadrangular space. To this point the operation in all such cases must be done very rapidly on account of hemorrhage. The downward and backward incision was now made from each inferior angle of the wound across the anterior

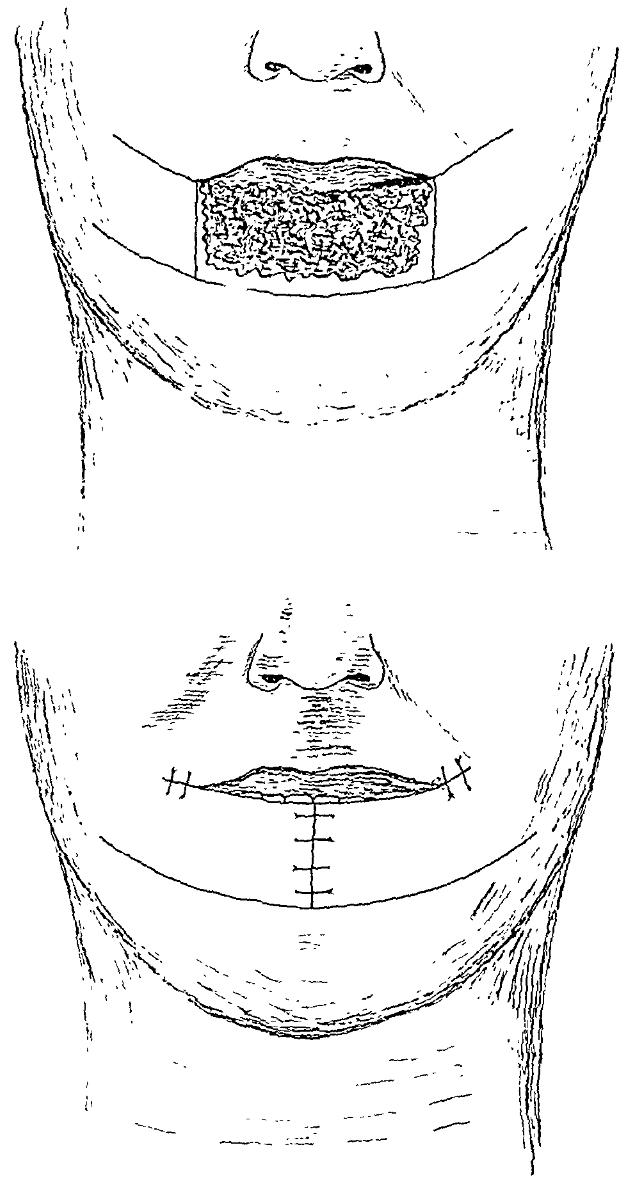

Fig. 1.—Malgaigne's method.

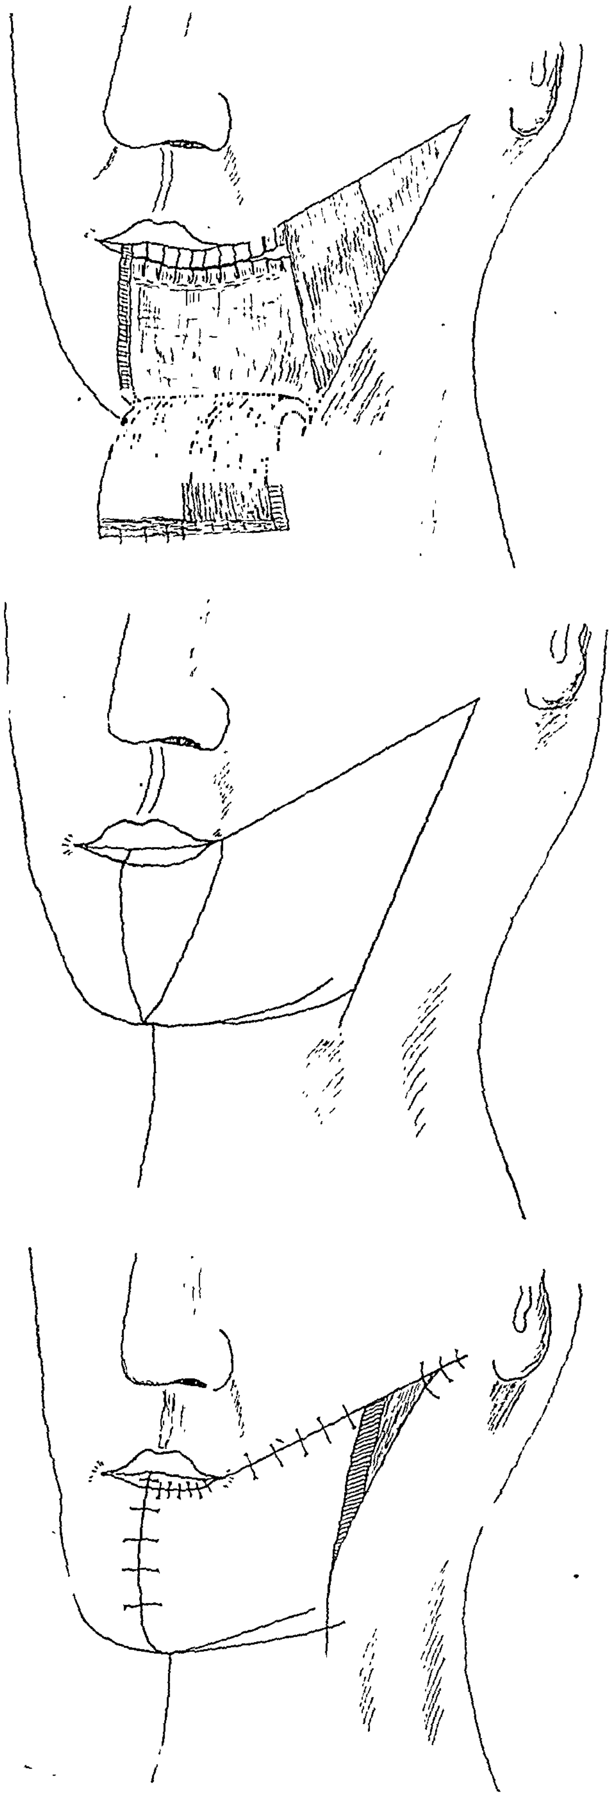

Fig. 2.—Dieffenbach's method.

triangle, the incision being longer on account of the immense gap to be filled. The cheeks were now separated from the inferior maxilla to the angles, cutting the facial arteries. In order to get free access to the extensive glandular involvement, I now made a transverse incision just beneath the apex of the chin, leaving a patch of skin an inch wide perpendicularly and nearly two inches transversely. The object of this being a fixed point to stitch the flaps to, a very important point in cheiloplastic work. The skin flap was now turned down completely from beneath the maxilla and anterior of the neck to the middle of the thyroid cartilage. The task of extirpating the glands was now begun. The superficial and deep glands, from the carotid sheath on one side to the other with hardly a break in the chain, were removed. The flaps for the mouth were now brought forward and united in the middle line with the aid of a mattress suture. Adhesive straps to the sides of the face, laced in front over gauze, may be used if deemed advisable to relieve the tension on the stitches. The operation at the angles of the mouth was now made as described, and the operation was complete, leaving not a gap to be filled by stitching, grafting or granulation. Drainage tubes were inserted in the posterior angles of the wound, and a slit in the flaps drained the submental space. Some infection of the flaps followed. This resulted in impairing the work at the corners of the mouth only, leaving the opening contracted some, but he could talk and eat with ease, and gained sixteen pounds in three months. I deferred securing photograph of mouth until I had an opportunity to repair the angles. This was postponed by the patient until he could make money to pay the hospital expenses. I kept track of him for six months after the operation. His health was good, with no recurrence. He then left Denver and I lost sight of him.

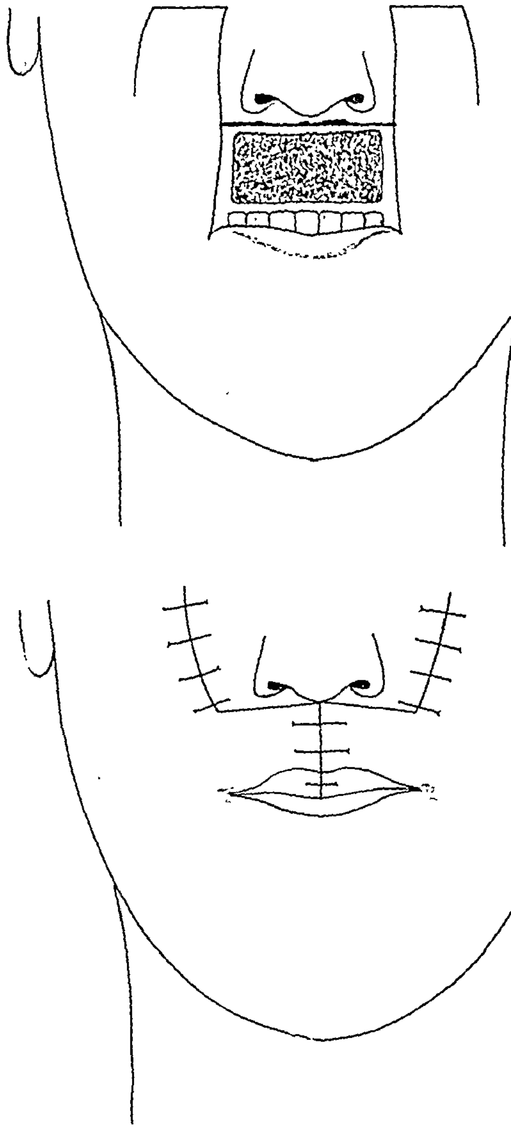

Fig. 3.—Dieffenbach's S-shaped method. Upper lip. Similar to Bruns for lower lip.

CASE 3.—M. A. P., aged 50, bookkeeper and commercial salesman. Carcinoma lower lip. Duration, two years. Operation March 30, 1904. Six months prior to operation treated by caustic pastes, which aggravated the condition, and he was advised to try *x*-ray treatment, but declined. The entire lower lip was involved and excised by the method described and used in all my cases. The submaxillary and mental glands were extirpated. The disease being confined to the lip and few glands being involved, the incisions were not so extensive, the gap not so large, and the operation more easily and quickly performed. The result was satisfactory, the mouth being normal in size and natural in shape. Patient is perfectly well, with no suspicion of recurrence.

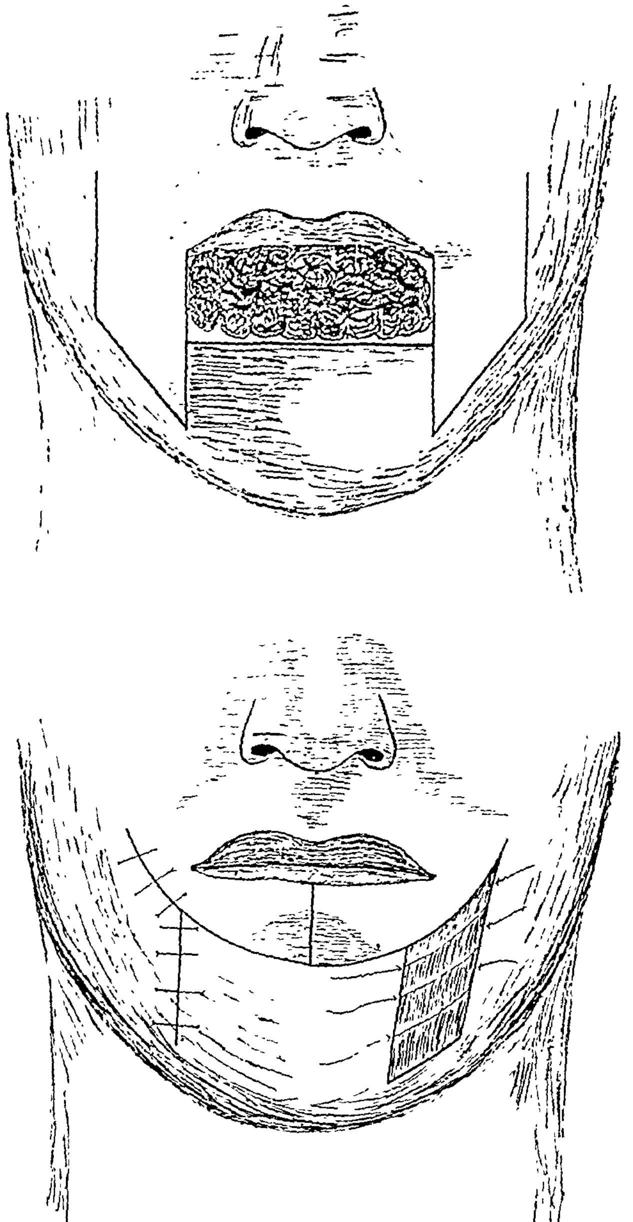

Fig. 4.—Sedillot's method.

CASE 4.—W. B. M., aged 67. Occupation, banker and farmer. Carcinoma, involving entire lower lip, of four or five years' duration; also had lupus of left lower eyelid and ulcer below temple, which healed under *x*-ray treatment. Same treatment of lip, for six or eight months before operation, but aggravated it. Base of growth hard and edges ragged and everted. Operation May 25, 1904. Same as preceding case. Submaxillary glands involved, the submental especially enlarged and hard. Mattress suture used in this case. Progress most satis-

factory. No infection except slightly at posterior angles. Primary union. Condition before and thirteen months after operation shown by illustrations. Local result excellent. No recurrence and general condition fine. Pathologic examination by Dr. W. C. Mitchell showed specimen to be carcinoma. I deemed this examination interesting and important on account of coexisting lupus of other parts of the face.

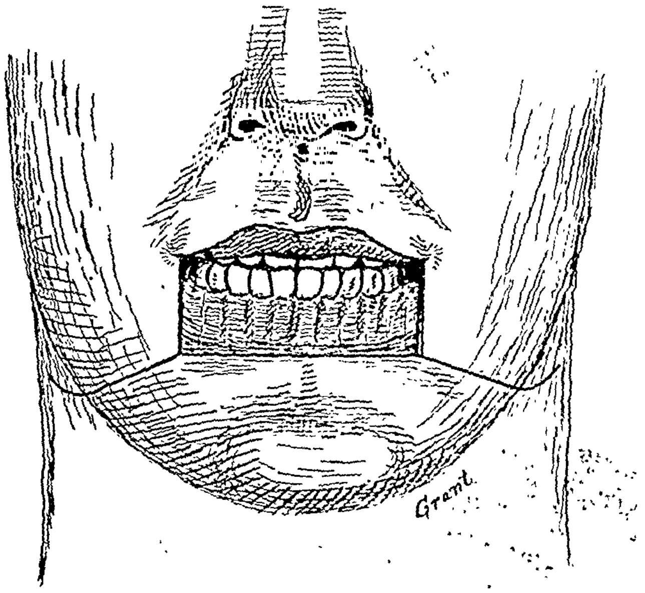

Fig. 9.—Second step of Grant's operation. The mass removed.

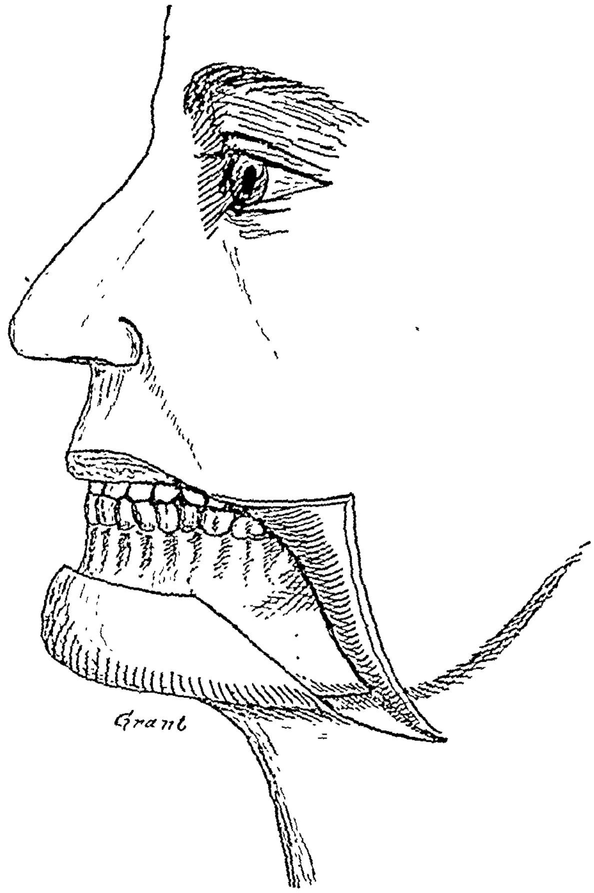

Fig. 11.—Dissection preliminary to suturing.

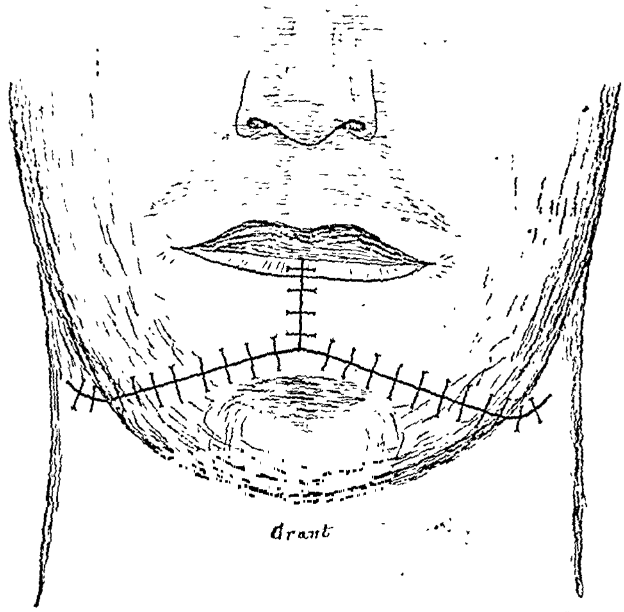

Fig. 12.—Sutured.

CASE 5.—W. N., aged 59, came from his home in Chicago to Denver to die among his children. He was referred by Dr. James Nevins Hyde to Dr. J. M. Blaine, of Denver, who referred the patient to me. The carcinoma involved the entire lower lip, extending slightly beyond the left corner of the mouth and invading the chin. It resembled very much in extent and appearance Case 2, but glandular involvement was much less extensive. Its duration is four years; it commenced as a small abrasion or ulcer near the center of the lip. Its progress was slow for a year or two. Three years ago it was treated by a paste in Chicago, and for some time was greatly improved. Beginning fourteen months ago it was treated for three or four months by *x*-ray in Chicago. This sensibly aggravated the condition. When presented to me in February last, it was an offensive, cauliflower-looking mass. Operation March 5, 1905, at *St. Luke's Hospital, Denver*, where the other operations were also performed. I was assisted in all the operations by Dr. R. G. Morrison of Denver. There was slight infection of the posterior inferior edges of the flaps in front due to imperfect drainage, and, perhaps, influenced some by the fact that the flaps, being slightly thicker than the chin tissues to which

they are stitched, perfect apposition of both edges is difficult of attainment. Yet this is not a serious matter, for drainage will protect the flaps. The further progress was satisfactory, union prompt and the result beautiful.

A few feet distant from the last three patients one would hardly observe that a serious disease and disfigurement had existed and that a severe operation had been performed on the mouth. The *x*-ray was advised and used in all cases for several months after operation. Before operation, when there is much thickening and hardening of the tissues, with implication of the glands, its use is harmful.

A CASE OF EXCISION OF THE CERVICAL PORTION OF THE ESOPHAGUS.*

WALLACE I. TERRY, M.D.
Instructor in Surgery, Medical Department of the University of California.
SAN FRANCISCO.

History.—The patient, M. K., aged 44 years, is a native of California and a farmer by occupation. Two years ago he was referred to me by Dr. George H. Powers, of San Francisco, on account of suspected malignant tumor of the larynx. A laryngo-fissure was done and the masses which sprang from the cords were removed, together with much of the mucous membrane of the larynx. The tumor was found to be an epithelioma. Four months later a recurrence necessitated another laryngo-fissure, at which time the wound was left wide open and *x*-ray treatment of the interior of the larynx was instituted. Despite this, the growth recurred, and in September, 1903, a total laryngectomy was done and the stump of the trachea sutured to the skin just above the sternum. Again, after five months, i. e., in February, 1904, a mass appeared in the scar and was excised. As these operations have already been reported,[1] no further details will here be given.

In June, 1904, the patient returned with a further recurrence in the scar, and on attempting to dissect it out it was found to involve the anterior wall of the esophagus to such an extent that an esophagectomy offered the only hope of its radical removal. The consent of the patient not having been obtained and no symptoms of obstruction of the esophagus having appeared, it was deemed best to defer such an operation. For eight and one-half months the patient lived very comfortably, using the phonation apparatus of Gluck, continuing daily hard work and not losing in weight or strength; then dysphagia became pronounced and he again consulted me. There was a tumor mass about the size of a goose egg in the median line of the neck, involving the hyoid bone above and extending laterally as far as the carotid vessels, and posteriorly the esophagus was invaded, while anteriorly there were two sinuses leading directly backward and discharging thin pus.

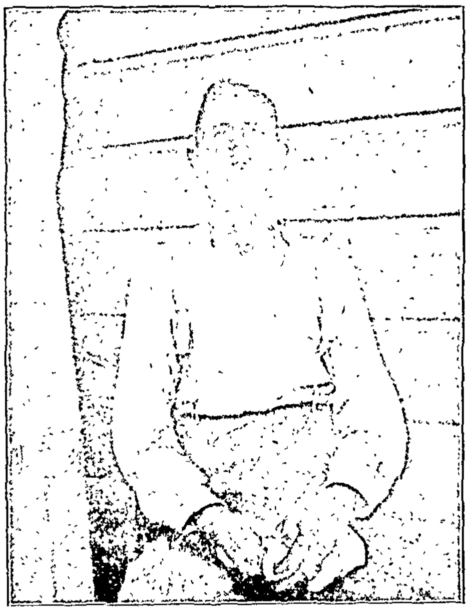

Fig. 1.—View of patient after partial esophagectomy.

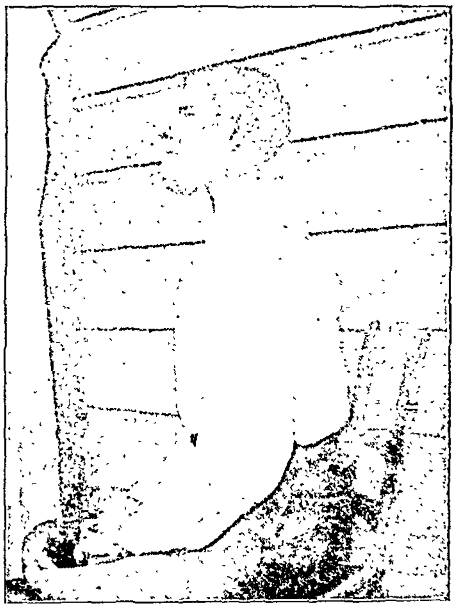

Fig. 2.—View of patient after partial esophagectomy.

In view of the facts that the tumor was slow in growth and that the general condition of the patient was so good, a radical extirpation of the entire mass was advised and agreed to.

Operation.—March 23, 1905, at St. Luke's Hospital, San Francisco. The anesthetic used was ether, given through a tube in the trachea, preceded by a good-sized dose of morphin and atropin. The incisions made were four—two lateral, extending from the angles of the jaw to within an inch of the clavicle and about 3½ inches apart, and two cross incisions above and below connecting these. Through these incisions a block of tissue embracing both submaxillary glands, the remnant of epiglottis, the hyoid bone, the anterior three-fourths of the esophagus, and the thyroid gland were dissected out en masse. The carotid sheaths were first exposed and found to be free of enlarged lymph nodes. Several vessels were here tied off, the principal ones being the thyroids. The two submaxillary glands seemed slightly infiltrated and were removed. Then the hyoid bone and epiglottis were freed by cutting through the muscles above them and opening the pharynx. Raising the mass, the esophagus was split longitudinally to below the thyroid gland. As only the anterior portion of the esophagus was involved, about one-quarter of the lumen was left posteriorly, with the expectation of creating a mucous surface to cover the cervical vertebræ. (That such a result was obtained is shown by the present appearance of the patient.) So much skin was sacrificed that it was impossible to bring the edges together, had such a procedure been considered advisable, so they were united on either side by catgut sutures, in part to the strip of esophagus and in part to the carotid sheaths. The muscles which had been attached to the hyoid bone were drawn together by a purse-string suture, and the mucous membrane at the base of the tongue was attached to the skin margin beneath the lower jaw. The opening of the pharynx was not closed with sutures, but lightly packed with gauze. Small cigarette drains were inserted in both superior angles. Hemorrhage from the operation was insignificant and shock was not pronounced. The next day the dressings were removed and the patient fed through a catheter passed down the esophagus. Thyroid extract, gr. 1 t. i. d., was also begun. Except for some slight infection of the wound and the necrosis of a portion of the mucous membrane at the base of the tongue, convalescence was uninterrupted. The patient was up and around by the fourth day.

---

* Read in the Section on Surgery and Anatomy of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

[1] Annals of Surgery, 1904, vol. 39, p. 968.

Subsequent History.—July 6, 1905. The patient was seen for the first time in two months. There is a mass just above the sternum which surrounds the upper end of the trachea and invades the esophagus slightly. The lumen of the trachea is only maintained by a silver tube which he constantly wears. He has, however, gained in weight and is but three pounds below his normal weight of 150 pounds. His general condition is excellent and he is able to do all sorts of work about a farm (Figs. 1 and 2). He masticates his food and swallows it by means of a simple funnel-shaped rubber tube, which is suspended above to the opening of the pharynx and below the narrowed portion enters an inch or two into the esophagus. With the kind assistance of Dr. James G. Sharp, of San Francisco, I had made a number of prothetic appliances of various materials and shapes, but we found that the rubber funnel best met the requirements. We also constructed another funnel with a valve, through which a phonation tube can be passed from the trachea to the pharynx. This is not very successful, however, as the air leaks back from the pharynx. Any apparatus which occludes the pharynx brings on a reflex spasm, causing nausea and hypersecretion of mucus and saliva. It is probable that this reflex can be brought under control by further practice, in which case a more satisfactory phonation apparatus can be employed.

I have considered the feasibility of forming a new anterior wall for the cervical esophagus, by means of skin flaps, but have rejected the idea because such flaps would have to be taken from some other part than the neck, and, moreover, they would mask the early evidences of a recurrence.

I did not temporarily close the pharynx, as advocated by some authorities, as I feared that sutures might imperil the integrity of the strip of esophageal mucous membrane, which I desired to leave.

It is to Gluck of Berlin that we owe so much in the technic of these extensive resections of the neck for malignant growths involving the larynx and the esophagus, and I feel that this paper would be incomplete without the mention of his name.

CANCER.*

W. L. RODMAN, M.D.

PHILADELPHIA.

Before proceeding to discuss the question of mammary carcinoma, it will not be far afield to consider the subject of cancer in general, especially its etiology and treatment, about which much has been written within the year, new claims having been made and old theories revived in modified forms. Perhaps the most notable communication on the subject of cancer during the past year was that of Doyen, who claimed not only that he had identified and made cultures of the germ, which he named the *Micrococcus neoformans*, but that he had prepared and used successfully in a number of cases a serum which was antagonistic to the parasite and curative of the disease. His claims have been reported on, favorably and unfavorably, by committees appointed for the purpose. The favorable report, not positive in its character, but mildly so, was made by Metchnikoff, a bacteriologist of commanding rank, but not a medical man, and, therefore, not a practical clinician. Other reports, and they have been more relevant and to the point, are adverse in every respect to the claims of this original surgeon. Attractive as the parasitic theory of cancer is and much as there is in its support, it can not be said that we are any nearer the goal than has been thought many times before. Possibly the strongest argument in favor of the germ theory of carcinoma is its supposed and apparent ever-increasing frequency in all countries where systematic records are kept, and that in this tendency barriers hitherto recognized, racial and geographic, are rapidly being broken down. In saying supposed increase, I do not mean to question the fact that cancer is increasing in America, England, everywhere, though there are many who do, and the observant must admit that this question, like all others, has two sides to it. When we reflect how common appendicitis, gallstones and gastric ulcers are to-day in comparison to what they were thought to be twenty-five years ago, when none of them were operable diseases, and, therefore, not studied with the accuracy with which they are at the present day, it is not difficult to see and to admit possibilities of error in cancer statistics. Who believes that appendicitis, gallstones and gastric ulcers are greatly more common to-day than they always have been? Who believes that they are vastly more common in one section than another? That minor differences, racial, dietetic and otherwise, are operative, perhaps to a certain extent, none will deny, but all will admit that each of the previously mentioned diseases has always existed about as commonly as they do at present. We look for them now and find palpable evidence of what we were formerly blind to. Is it believed that gastric ulcer and gallstones are more common in one section of the country than in other parts of America? Yet two surgeons in a small town of Minnesota have reported 1,000 operations for gallstones and half as many for ulcer. They have been pioneers and epochmakers in gallstone and gastric surgery, and have taught the rest of us how many such cases we have necessarily overlooked. So it may be with cancer. Certainly many cases now clinically and microscopically demonstrated to be cancer would formerly not have been thus recognized and recorded. On the other hand, as many, perhaps more, cases formerly denominated cancer are now easily demonstrated by the microscope to be sarcoma, actinomycosis, tuberculosis, syphilis, etc.

Simultaneously with the announcement of Doyen's discovery, there came a strong article before the Surgical Section of the International Congress at St. Louis, September, 1904, from Professor Orth, of Berlin, combating the germ theory of carcinoma and announcing his adherence to the cellular theory in the most positive way. It is very clear that if parasites are present they are intracellular and play a secondary, and not the chief, rôle as an etiologic factor. They certainly do not and, according to Orth, it is simply impossible that they should, bear the same etiologic relation to cancer that the bacillus of Koch does to tuberculosis, and that pyogenic cocci do to suppuration. The language of Orth could not be stronger and, considering its high source, is, therefore, quoted verbatim:

> In order to produce pus, or tuberculosis, etc., it is sufficient for the pus cocci. or tubercle bacilli, to reach suitable media; to bring about a secondary cancer it is absolutely necessary that cancer cells from the primary or from a similarly created secondary tumor shall reach the particular spot, and there continue their growth. In the case of secondary cancers we have to do with a successful transplantation of cancer cells; in the case of pus foci, or tuberculosis, there occurs a transplantation of the parasites, which do not themselves form the new focus, but they impel the local tissue, without any coöperation of the tissue of the primary focus, to certain pathologic changes. Therefore, there is an important difference between these two classes of phenomena; and one can not conclude, that since in the case of pus foci, tuberculosis, etc., parasites play a rôle, this must also necessarily be the case in the carcinomatous new growths; *one can say*, however, that if in cancer parasites should happen to play a part, then these

* Read in the Section on Surgery and Anatomy of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

> parasites must be of an entirely different kind than those above mentioned, because they must bear the closest relationship to the cancer cells which characterize the growth. I do not consider it impossible for an intracellular parasite to play a part here; but it is impossible for it to play an independent part. It can not possibly in itself be the decisive factor in the new growth; it can not determine the variety and character of the new growth, since the cells themselves, and only they, do this.

The transmission of a cancerous tumor from one individual to another, though often cited as evidence of the parasitic nature of the disease, proves absolutely nothing further than that a successful grafting has taken place. The tumor thus formed is the result of the multiplication of the cells introduced and is analogous in every way with epidermis when transferred from one person to another, as in skin grafting. Until cultures from the supposed germ can, alone and of themselves, independent of cells, cause a primary tumor, it is useless to insist on the infectious nature of the disease. Cases of so-called autoinfectivity prove even less, for here the host has tissues admittedly prone to epithelial degeneration, and it is easy to understand how a successful graft can follow prolonged contact.

The rarity, if not unheard of, infection of operating surgeons by cancerous patients is the strongest possible evidence against the parasitic nature of the disease. Even, however, if the parasitic nature of cancer were established beyond question, we should still be largely in the dark as to other essential etiologic factors. Every one in densely populated cities is probably daily exposed to the tubercle bacillus, and yet only a small minority are affected with tuberculosis.

That the old theory of continued irritation of epithelial tissues is almost, if not quite, necessary to explain the development of cancer I do not question. One has only to reflect that all forms of carcinoma are very generally found at points subject to persistent irritation, viz., the lips, tongue, esophagus, stomach, cecum, rectum, uterus and mammary glands. At least one excellent book has been written during the last year emphasizing the importance of heredity as a predisposing cause of cancer and showing that at least one-third of all these patients give a cancerous history. There is no question, I take it, that, with the passing of the constitutional theory of cancer and the demonstration and acceptance of its local origin, about thirty-five years ago, there began a tendency to minimize the influence of heredity as a predisposing cause. This has been carried too far, just as has been the case with tuberculosis. The disease, of course, is not inherited, but the soil is prepared and made ready should the seed be sown at a time when epithelial tissues are prone to run wild.

That race, environment, temperament, habits, trauma and possibly diet are at times influential may be allowed, but it would seem that more than one cause is usually operative.

PRECANCEROUS CONDITIONS.

Much is written, more is thought, judging by statements one hears made in private conversation and from discussions in medical societies, concerning the precancerous state, yet comparatively little seems based on indisputable facts. We hear a great deal about malignant degeneration of benign tumors, and, while it does occur, though much less frequently than is generally supposed, a careful investigation reveals the fact that very generally it is sarcomatous and not carcinomatous degeneration. Beyond the fact that superficial moles and warts, congenital or acquired, not infrequently late in life undergo malignant transformation, there is little trustworthy evidence.

J. C. Warren[1] reported a series of cases of breast cancer, 100 in number, and in only a single case was there the slightest evidence showing that a benign growth had undergone cancerous change. A small fibroma, the size of a horse chestnut and of twenty years' duration, became the seat of carcinomatous change.

I know of no other series of cases so accurately and conscientiously reported, and nearly all were examined by one microscopist of national repute, Dr. W. F. Whitney. If such malignant transformation can be shown but once in a hundred cases of breast cancer, the region of all others where it is supposed to occur most frequently, are we not, in recognizing its possibility, too strongly accentuating the probability of such change? According to Mr. Raymond Johnson, of London, the general opinion that breast tumors originally benign are prone to degenerate into malignancy, is incorrect and can not be proven. In a series of lectures delivered at the Royal College of Surgeons, of England, Mr. Johnson devoted considerable time to combating this well-nigh universally accepted view. He asserts that adenoma, which is by most authors supposed to be exceedingly liable to cancerous change, never does so, and says that no one has ever reported a case where an encapsulated tumor, as the adenoma, has been seen bursting through its capsule and infiltrating the surrounding tissues. Until he has seen such specimens and examined them macroscopically and microscopically he can not believe they are of common occurrence, if, indeed, they exist at all.

PAGET'S DISEASE.

There is, perhaps, no opinion more general or more tenaciously adhered to by physicians, surgeons and pathologists than the one that eczema or psoriasis of the nipple and areola, the so-called Paget's disease, frequently leads to cancer. The commanding position of the surgeon first promulgating this view at once caused it to be generally accepted and taught. In a paper read before the Surgical Section of the American Medical Association at Baltimore in 1895,[2] I questioned the accuracy of the observation and expressed the opinion that the Paget's disease was secondary to tubercular cancer and that the discharge from within caused the irritation without. Since then I have operated on one patient with Paget's disease, and it was undoubtedly secondary to duct carcinoma. This is the only case of Paget's disease that has ever come to operation at my hands and, in a measure, confirms the theoretical opinion I had formed. This question has become an acute one since the excellent Bradshaw lecture of Mr. Mayo Robson, of London, in December last, in which he made a strong plea for operation in the precancerous stage. His position has been challenged by several, notably by Roger Williams, who states that in only 0.5 per cent. of areolar diseases is there subsequent cancer. Two thousand cases were analyzed. Of the 100 cases of Warren, there was but one in which Paget's disease was or had been present; so at most the association between the two conditions is infrequent, and, when it does occur, the probabilities are that the external areolar disease is secondary to, and not the cause of, duct cancer. This view is supported by the investigations of Thin, Roger Williams, Raymond Johnson and others.

PHIMOSIS.

As fixed in the professional mind is the belief that phimosis is frequently antecedent to and causative of cancer of the penis. This would seem theoretically to be so, but is it?

Phimosis is too common a condition the world over and cancer of the penis too rare a disease for there to be any close connection between them. Less than 1 per cent., according to the registrar-general's statistics, of the deaths from cancer in Great Britain resulted from cancer of the penis.

In 1898, in my Chairman's address[3] before the Surgical Section of the American Medical Association, I called attention to the rarity of cancer of the penis in negroes. I have never seen a case; none had been treated in the Louisville City Hospital, and the recorder of the health office for the city of Louisville for a period of thirty years recorded no death from cancer of the penis in a negro. I also pointed out that the negro far more than the Caucasian was affected with phimosis; in fact, almost universally so and often to an extreme degree.

The census statistics of the United States for 1900 are even more cogent and to the point and show that, although the death rate for male negroes was 28.6 per 100,000 living, no death resulted from cancer of the penis.

This can not be explained by racial insusceptibility, for the African is more liable to both cancer of the uterus and of the mammæ than the Caucasian.

Further, the Jews, according to Roger Williams, are as liable to cancer of the penis as non-Jews. There is, at most, only a potential relation between phimosis and cancer of the penis.

In his position that gallstones may cause cancer of the gall bladder, I believe that Mr. Robson stands on ground better chosen, and yet we should not forget how rare primary cancer of the gall bladder is and how frequent gallstones are, occurring, it has been said, in 10 per cent. of all persons examined at autopsy. It is doubtless true that in only those cases of infection and chronic ulceration, with its subsequent cicatricial tissue, of the gall bladder that the danger of cancerous implantation is great. Too many such instances are reported by accurate observers to be ignored. It is only of recent years that gallstone disease has been studied with care and accuracy, generally followed by operation, and supplemented by careful microscopic examination of the viscus when cholecystectomy has been performed. That increasing and incontrovertible evidence sustaining Mr. Robson's position will be forthcoming, now that cholecystectomy is so frequently resorted to, I have not the slightest doubt. The statistics controverting this view cited by Mr. Williams and others are convincing to those who rely entirely on statistics, but, as I have already said, it should be recalled that we are almost at the very threshold of any accurate knowledge on the subject of gallstone surgery, and old statistics, while not valueless, are not necessarily conclusive.

ULCER OF THE STOMACH.

While the possibility of gastric ulcer terminating in carcinoma has always been admitted since Cruveilhier's classical work in 1839, it is only recently that such change is believed, anl only now by a few, to be frequent. Opinions have yet to be crystallized on this point. Zenker thinks that practically all cancers originate in ulcers, whereas his pupil, Hauser, estimates that only 6 per cent. of all carcinomata have their origin in gastric ulcers. Mayo Robson performed gastroenterostomy for cancer 64 times, and in 38 (59.3 per cent) there was a "long history of painful dyspepsia suggesting the possibility of ulcer preceding the onset of malignant disease." Of 157 patients with gastric carcinoma operated on by William J. and Charles H. Mayo, 60 per cent. gave a good history of previous ulcer, almost exactly the same number shown by Robson's experience. The opinions of such experienced clinicians and practical surgeons are far more weighty, because they are reinforced and confirmed by direct exploration, than merely theoretical opinions or even observations made at autopsy. I called attention to this point in the Address in Surgery[4] given before the American Medical Association at Atlantic City in 1900. Subsequent experience has taught me to believe that a greater number of ulcers than I even then supposed undergo malignant transformation.

The topography of ulcer and cancer is the same, and there is no room to doubt that many of the latter have their inception in the former. This is one of the strongest possible reasons for the surgical treatment of all chronic or rebellious ulcers, preferably by excision of the ulcer, or, if multiple, of the ulcer-bearing area, pylorectomy. Gastroenterostomy, satisfactory as it is for a time, does not remove the lesion and, therefore, prevent malignant change. I have never doubted that it must, in such cases, either give way to or supplement more radical procedures.

The frequency of cancer of the cecum, and the fact, now pretty well established, that it often begins in the appendix, is an additional reason for removal of the organ when it has suffered repeated attacks of inflammation. I have operated twice in elderly men during the past six months for advanced cancer of the cecum and the evidence was positive in one case, and next to it in the other, that the malignant disease had its inception in the appendix. That cancer frequently originates in the inflammatory and cicatricial tissues about the caput coli, resulting from previous appendiceal attacks, I have not the slightest doubt. So this already fertile surgical region has within the year become of even greater interest on account of the fact that tubercular peritonitis often has its beginning in a tubercular lesion of the appendix, as demonstrated by Mayo, and the further probability that carcinoma not less frequently has its inception in a neglected chronic inflammation of this viscus.

It will be seen later that no one believes more than I in early, as early as possible, and complete operation in malignant disease, but I do not go so far as to advise operation in many of the so-called precancerous states. It is first necessary to show that a precancerous state exists and then our duty becomes reasonably clear. I would not operate on a leucoplakia of the tongue or lips, because such condition has been supposed to invite epitheliomatous change. I have seen hundreds of epitheliomas about the mouth, and have no trustworthy evidence that any, if preceded, resulted from leucoplakia. I certainly would not operate in a case of Paget's disease in a young woman of child-bearing age on account of any tendency *per se* for it to be followed by cancer. I would operate on a chronic ulcer of the stomach, preferably excising it, for the evidence here is more convincing. Further, aside from the danger of cancer, there are other even greater hazards, as perforation, stricture, dilatation, hour-glass stomach, etc.

We have been told that it is also best to operate in the preperforative stage of typhoid fever. Most of us, I fancy, find it difficult enough to make a diagnosis when perforation has actually occurred. If in doubt we should perform an exploratory operation, and the same rule should obtain in suspected cancer, the danger of delay being immeasurably greater.

MAMMARY CARCINOMA.

Diagnosis.—He who advises a woman with a tumor of her breast, especially a woman past 40, to wait and see if it be malignant is guilty of an unwarrantable and, therefore, censurable act. If he can not make a diagnosis there are others who can in nearly every case, and in all cases, by a perfectly easy, safe, and quick exploration. Let the public be educated, as they will be in time, to believe that an early diagnosis and prompt operation are both as necessary. I go further, more necessary in cancer than in appendicitis, for the latter may recover, and frequently does, without an operation, the former without surgical intervention inevitably leads to one of the most painful, lingering and loathsome of deaths. We are just beginning in America to see an awakening on the part of laymen to the hazards of appendicitis, and nearly every enlightened person knows something of its symptoms, its dangers, and the conservatism of early operation. Though the surgeon be ever so assiduous and discrete in his efforts to shield the practitioner who has dallied with the case, as is so frequentl done, the patient and his family hold the physician, not the surgeon, responsible for an adverse result. Physicians realize this and, having become more astute diagnosticians in this affection, advise early and, therefore, safe operation. There has been a most remarkable improvement in this respect in Philadelphia in the past few years. My own experience shows but 3 pus cases in 49 operations for appendicitis, most of them acute, since Sept. 1, 1904. That all were successful is largely due to the fact that, in most instances, an early diagnosis was made. In this disease we are far ahead of the English and Continentals. I was surprised to find, three years ago, that cases of appendicitis going to some of the very best English hospitals were sent to and kept in the medical wards until pus formed, when they were considered for the first time surgical cases and transferred. While this is true, however, the English are keen on the subject of cancer; they have studied it carefully and, as a general thing, rank and file, are more alive to the possibilities of surgery for its relief than are we. I am satisfied that practitioners throughout Great Britain are more impressed with the importance of and do make earlier diagnoses in breast cancer than is the case with us.

The late Sir Mitchell Banks, while I was his guest in Liverpool last July, assured me that there had been an enormous change in his practice in this respect in the preceding five years. I saw him do several operations and all were early, what we would call good operative cases. In none was there an evident tumor to the eye, though distinctly so to the touch. Two patients had moderate axillary infection of the lower glands, one little, if any, glandular involvement at all. Remarking on the favorableness of his cases, he told me of the great change for the better which had come in recent years. We can not say that this is only true of Liverpool and its environs where the great influence and teaching of that forceful and charming man were most directly felt. Everywhere I went it was the same, and I now understand, better than I could before, the operative results of English surgeons. Although the radical method of operating for breast tumor was introduced by Moore, of the Middlesex Hospital, in London, in 1867, the English were slower than the Germans, Austrians and Americans to give attention to the teachings of Moore and to put them into practice. Banks, of Liverpool, was an early champion of Moore's operation, which consisted in a large incision, free removal of skin, sacrificing the entire gland in every case, and a free axillary dissection. The muscles were not disturbed, not even the fascia covering the pectoralis major. This step was introduced by Volkmann a few years later. The English were particularly sensitive about the most important step of the operation, a free axillary dissection and removal of all diseased glands and fats. They both overrated its danger and underrated its necessity. Notwithstanding the fact that they were slow to put into practice the teachings of Moore, Banks, Volkmann, Grass and Halsted, their ultimate results were as good as those of the surgeons of other countries. This can only be explained in one of two ways: First, incomplete operations are as satisfactory in their ultimate results and yield as great a percentage of cures as complete operations; second, their patients were operated on earlier. Certainly no one believes the first proposition. At the present time, and it gives me pleasure to record it, as many, perhaps more, English surgeons are doing a thorough operation, usually Halsted's method, than is the case with us.

In addition to the usual signs and symptoms of cancer of the breast, there are two methods by which a positive diagnosis can be made: 1. Aseptic incision into the tumor has been advocated and practiced. It is neither accurate nor safe, and many cases have been reported in which infection of the adjacent tissues occurred through cells and juices thus liberated. It is unquestionably a dangerous practice unless followed by immediate operation. 2. It is much better to get the consent of the patient to a complete operation in all cases where malignancy is suspected, provided both macroscopic and microscopic examination prove it to be necessary. A competent microscopist is asked to be present, and in ten minutes he can give a reliable opinion as to the nature of the growth. During the short period of waiting, the wound should be plugged with gauze, the knife and instruments which have been used laid aside, and the hands of the operator again sterilized. It is best to send either the entire tumor to the pathologist (or to cut a portion from its center). If the report comes back *benign,* nothing further is necessary beyond suturing the wound; if *malignant,* a complete operation, preferably by Halsted's method, should at once be done. I have used this method for many years, have never known ill result from it, and by it, moreover, have, more than once, been saved the possible humiliation of removing needlessly a breast in young, child-bearing women. Twice have I been made to recognize cancer in two of the youngest subjects I have ever operated on, 23 and 27 years of age, respectively, when it had hardly been suspected. One of the best disquisitions on this subject to which I have listened or of which I know was by J. Clark Stewart[5] in his paper before the Surgical Section of the American Medical Association in 1904. I can not understand why this practice is not a more general one. It is practicable, of course, only in a hospital, it is a little troublesome and is tedious on account of arranging for and awaiting the pathologist's report. There is, moreover, I admit, the bare possibility of autoinfection when the surgeon is careless, leaving an open wound and failing to resterilize instruments and hands; but these objections are as nothing, mere trifles as light as air, in comparison to the weighty reasons for an absolutely safe diagnosis, that it may be followed immediately by a complete operation. If we limit the exploration to aseptic incision, closing the wound and waiting indefinitely to remove the breast, if malignant, then the objections that have been made are quite to the point. Such practice can not be too pointedly condemned. Aside from its immediate dangers, this procedure encourages procrastination, and this, in mammary growths, is always hazardous. Removal of the entire growth with capsule, if there be one, in the absence of a capsule the adjacent tissue, then plugging the wound with gauze and waiting ten minutes is an entirely different proposition; yet the two procedures are generally, almost always, confounded, and the palpable and admitted dangers of the one have lessened the popularity and usefulness of the other.

---

[5] The Journal A. M. A., Aug. 6, 1904, p. 365.

Prognosis.—There are three conditions, none of them sufficiently dwelt on by authors and, therefore, not appreciated as they should be by operators, materially influencing the prognosis of mammary carcinoma.

1. The pathologic variety of the growth, more than anything else, influences the prognosis for better or worse. The tendency to axillary and other lymphatic involvement is much greater in both encephaloid and scirrhus than in adenocarcinoma; hence, the more favorable results of operations for the latter.

2. The age of its host materially influences the rapidity of a mammary cancer. In the young, lymphatic vessels are numerous and patent, whereas in the old many have atrophied. Therefore, metastases occur quickly in the young, often before they are suspected, and this fact should prevent procrastination and encourage complete removal. For a better understanding of the lymph-bearing vessels of the breast in the young and old relatively, we are mainly indebted to Charles H. Mayo, Poirier and Cuneo.

3. When carcinoma involves either of the sternal quadrants or the inner hemisphere of the gland, other things being equal, the prognosis is worse than when it is in growths suited in the outer hemisphere or axillary quadrants. This is due, of course, to the danger of mediastinal infection. I must here insist, as I have done on former occasions, that malignant growths are more frequently thus situated than is generally believed.

Treatment.—It is easier to understand than to excuse the pessimism still too frequently expressed by surgeons, as well as physicians, as to the curability of cancer by operation. Some, fully abreast with the times in other respects, are far behind in this one. Internists can not be blamed for their lack of faith when surgeons frequently, and teachers occasionally, express doubts as to the beneficent results of a timely operation. There are some doing abdominal operations which were known five years ago, and yet they are apparently ignorant of the possibilities of a rightly done operation for cancer. This is most unfortunate, as it encourages physicians to undervalue the importance of exactness in diagnosis when the growth is strictly local and, therefore, entirely amenable to operation. Moreover, it encourages the running after false gods, the chief of which is the treatment by *x*-rays, which is responsible for the loss of many valuable lives that might easily have been saved. It is almost inconceivable that relatively so few surgeons are doing a complete operation for mammary cancer. Yet it is eleven years since the publication of Halsted's epoch-making paper containing the most positive and convincing proof as to our duty when dealing with this pitiless enemy of womankind, and thirty-eight years since Moore advocated not so complete a procedure it is true but still a far more radical operation than is frequently seen at the present day. Operations for mammary cancer if performed, as they should be, in the first stage when the growth is small and strictly local, should furnish 75 per cent. and upward of cures. This is even less favorable than operations for cancer of the lip.

In cancers of the second degree in which the neoplasm has become adherent to adjacent tissues and in which there is moderate axillary involvement, the condition nearly always encountered at operation, are curable in 50 per cent. of the cases.

In cancer of the third degree, in which the entire breast is adherent to the chest wall beneath and the enlarged axillary nodes have coalesced into one large mass, possibly adherent to everything about them, but little can be promised. Still, operation should be undertaken, for now and then an unexpected cure is witnessed. I have had one such case myself, and recently Prof. W. W. Keen told me of a case of his in which he at first declined to operate; the cancer was so far advanced. Yet a complete operation gave perfect relief, and the woman died five years later of apoplexy, entirely free from recurrence.

The experience of another year has increased the conviction expressed in my paper before the British Medical Association at Oxford, in 1904, that the supraclavicular glands should be explored and removed, if enlarged, in all cancers situated in the upper hemisphere of the gland. It has been shown by Poirier and Cuneo that a chain of superficial lymphatic vessels passes from the breast directly over the clavicle and empties into the glands in the posterior triangle of the neck. In three such cases treated in the past year all were explored. In one there was unmistakable involvement, in the other two absolutely normal glands and fat were found. Unless there is macroscopic involvement I do not make an elaborate dissection of the neck, as I believe it to be unnecessary and to prolong needlessly an already lengthy procedure.

Extensive as these operations seem, and really are, the operative mortality can almost be ignored, as it is less than 1 per cent.

DISCUSSION

ON PAPERS OF DRS. GRANT, TERRY AND RODMAN.

Dr. J. G. Sherrill, Louisville, Ky., said that two years ago he presented a report of two cases of cancer of the intestines and was surprised to find that this condition is quite frequent. The resemblance of these cases to appendicitis is often noticeable. The glandular involvement which so frequently follows cancer is not present in carcinoma of the intestines. Sarcomata of the gut shows involvement of the lymphatic glands in the neighborhood, which is not generally believed to be true. He agreed that exploration of the breast is a dangerous procedure unless the breast is removed immediately thereafter. He has abandoned these explorations. Making a diagnosis before operation is very important, and he operates by beginning always in the axilla. If this were done constantly better results would be attained. An incision may be made into the breast and the procedure mentioned by Dr. Rodman followed with good results.

Dr. J. E. Boucher, Hartford, Conn., reported six cases of resection of the bowel for cancer; all the patients recovered from the operation, but one died later from a recurrence. Five of the six operations for resection of the bowel were for cancer. Five of the operations were performed without any contrivance save a needle and silk, the other with a Murphy button. Five patients are living after intervals of from two months to three years. All have been comfortable. Two of these cases were advanced, one involving the abdominal wall; in one which seemed hopeless the patient lived for six months and died from recurrence. It would seem that it is much better to resect and to remove cancer of the bowel, even at a late period, if at all operable, rather than to do a simple anastomosis around the growth, as the latter procedure at best promises very little in the way of increased length of life and, after all, is quite as dangerous as a complete removal with anastomosis. These cases all seem to indicate that complete removal of the growth is advisable on account of the slow return of some varieties of malignant growth involving the intestines.

Dr. C. O. Thienhaus, Milwaukee, Wis., does not remove a wart because it might become malignant. For cosmetic reasons, or if inflammation or irritation is present, warts should be removed. Since it has been definitely proved that all the lymph channels of the breast unite on the deeper fascia, it has become an absolutely essential factor of operative procedure to remove the pectoral major and minor muscles, and it has been somewhat surprising to Dr. Thienhaus that an attempt has recently been made to save a part of the pectoralis major muscle for the purpose of supporting the function of the arm. Furthermore, since it has been shown recently that lymph channels to the epigastric region exist which must be held responsible for the not so seldom found recurrence in the epigastric region it may be essential to extend the incision to the linea alba for the purpose of dealing with this lymphatic extension. In regard to the diagnosis of cancer of the breast, if there should be any question at all before operation, Dr. Thienhaus believes that a freezing microtome used during operation may sometimes give us the needed information.

Dr. J. J. Hamilton, Caldwell, Idaho, said that he has an old man under treatment for cancer of the rectum, who suffers very much. He does not expect to get well, but he wants to suffer as little as possible, and Dr. Hamilton would like to know what to do for him. He does not think a man of 71 could stand an operation. Although the patient is still living, Dr. Hamilton would like to have some idea of the probable length of time he is likely to be able to hold out. Would the creation of an artificial anus be wise?

Dr. J. Clark Stewart, Minneapolis, Minn., said that he knows of no operative procedure so generally neglected as a properly devised one against lip epithelioma. Epitheliomas are disseminated through the lymphatics like other carcinomata, but much more slowly. Physicians can never say by any examination that dissemination has not yet begun, and for this reason it is imperative to remove the lymphatics in every case, just as is done in the Halstead breast operation. An ideal operation against malignant disease must include certain factors. First, sufficient tissue must be removed immediately about the malignant growth: second, all lymphatics and nodes must be removed without section in one mass with the primary growth; third, a suitable plastic procedure should be done so as to secure union by first intention. Dr. Grant's operation fails in violating the second point in cutting across the lymphatics, as they run downward from the lip. Dr. Stewart has been doing and teaching for the past six or seven years a somewhat similar operation which avoids this fault. He carries the deep incisions on each side of the growth down to the point of the chin, and then backward and outward under the line of the jaw far enough to expose the submaxillary glands. These lateral incisions are then joined by one cutting the skin only, and the whole skin flap is dissected free down to the hyoid bone. From this point the connective tissue, lymphatics and lymph nodes are dissected upward in one piece, including the submaxillary glands, and the accompanying lymph nodes on each side, and last the portion of the chin between the original incisions, including the epithelioma, is cut loose from the underlying jaw. He finishes the operation as Dr. Grant has described his procedure and finds the cosmetic results very good, indeed. With this operation done early, recurrences should be very few, indeed, a striking contrast with the V operation, which deprives the patient of all chance unless the lesion is purely local.

Dr. A. McGlannan, Baltimore, said that in cancer of the breast we have about reached the limit of operative interference. Any improvement in ultimate results will be due to earlier diagnosis. Every single tumor of the breast should be explored. If it is benign, it could not be removed at a better time. The recognition of cancer by exploratory incision can be done by the naked eye. If the appearance of benign tumors is known a malignant one can readily be recognized, although in the breast the recognition of parenchymatous hypertrophy may be difficult. With practice, however, this can be learned, and it avoids waiting for the pathologist. The naked eye is just as good as the frozen section, and is safer because instantaneous. When cancer of the breast is found it should be immediately operated on. The glands of the neck should be taken out in all early cases. If the nearest chain of glands is not removed the operation for cancer is only palliative, and a cure is more certain to result if the glands are removed. One symptom of onset in cancer of the breast is pain, and pain in connection with a lump in the breast is frequent, so that women come complaining of the association of these symptoms. Dr. McGlannan would not make a diagnosis of carcinoma simply from a pain in the breast, but if the pain is present for three months, and there is no tumor to be found, the physician can safely say it is not cancer, but probably neuralgia or something of that kind.

Dr. Martin, New Orleans, recently was surprised to find that Dr. Warren's statistics give cancer of the breast as being rare in the negro, as statistics in New Orleans show that they are about equal; although the negro is less liable to come for treatment. Dr. Martin believes the negro is more likely to have this disease than the white. He has seen about 200 patients and operated on 80, but every now and again he has to refuse operation. If one only stops to think of the ramifications of the lymphatics, operation would be done only with the idea of relieving pain. The absolute necessity of removing all neoplasms of the breast as soon as they are discovered is a good point, and Dr. Martin called attention to this, as he does not think they should ever be allowed to remain. Physicians and the public alike should be educated. The gynecologists have educated their patients to the importance of tumors, and surgeons should do the same.

Dr. A. H. Levings, Milwaukee, said that it is pretty well established that traumatism, chronic irritation and chronic inflammation are at least predisposing causes. It has seemed to him that the long continued hyperemia incident to these processes with the return of the cells to their embryonal state, their rapid proliferation and unstable condition, might explain the sequence of events in many of these cases. In three cases of cancer of the penis that have come under Dr. Levings' observation there was in each a long adherent, troublesome prepuce. He could but think in these cases that the long-continued irritation was at least a predisposing factor. In regard to the relationship between cancer and tuberculosis, it has generally been held that there is a certain antagonism between them. This seems to be incorrect, for postmortem records show that healed tubercular lesions are quite frequent in persons who have died of cancer. The family history of two brothers who consulted Dr. Levings a year ago with carcinoma of the stomach gave him food for reflection in regard to the relationship between cancer and tuberculosis. In the family there were seven children, with two, probably three, suffering from carcinoma of the stomach. The mother died at the age of 39 with pulmonary tuberculosis. The father remarried. The second wife had eight children, and she and the children are all well up to the present time. Since that, in so far as possible, Dr. Levings has carefully taken the family history of every case of carcinoma that has come under his observation; 70 per cent. show a family history of tuberculosis, whereas in non-cancerous individuals a tubercular history is present in only 25 per cent. of the cases. Some patients showed the two diseases to have been present in the same individual, either at the same or at different times. In one there was, when 5 years old, a tubercular inflammation of the hip joint, with abscesses and destruction of bone. The process healed after two and a half years. At 40 the patient had carcinoma of the breast. Another patient had chronic inflammation of the knee joint when a girl. The process became arrested after a year, and at 50 the patient had cancer of the breast. Two patients had lupus, and after several years an epithelioma was engrafted on the lupus patch. Dr. Levings thought that Koch's bacillus, working within the tissues even of the ancestors, might leave such a cellular weakness as to predispose the individuals subsequently to the cancerous condition.

Dr. Emmet Rixford, San Francisco, declared that there is no question of the truth of the dictum of Watson Cheyne, "the patient's chance is in the first operation," and, therefore, the earlier and the more radical the removal of the cancerous breast the less the probability of recurrence. Patients with recurrence are not altogether in a hopeless condition. It is a matter of common experience that when the axilla is carefully cleaned out, even if it contained extensive metastases, further dissemination in that direction is frequently stopped. The majority of recurrences take place in the scar, but a considerable number alongside the sternum. Dissemination toward the mediastinum is stopped by the mediastinal glands, and it would seem to be possible in some cases to remove these glands sufficiently radically to prevent further extension, just as in the case of axillary metastasis. It has been Dr. Rixford's lot to see a number of cases in which the only detectable recurrence after radical operation was at the edge of the sternum. Resection of a portion of the chest wall in these cases showed that the tumor had penetrated the wall, but had not involved the lung or pericardium. In three cases mediastinal glands and fatty tissue were resected. In four cases in which resection of the chest wall was performed two patients are free from recurrence at the end of six months, and one at the end of two years. In five operations there was no mortality and no serious trouble incident to the acute pneumothorax.

Dr. F. W. Parham, New Orleans, called attention to a plastic procedure described in the *Deutsche Zeitschrift für Chirurgie* a few months ago. This procedure is that of Schulten and consists in borrowing from the upper lip a sufficient breadth of mucous membrane and submucous muscular tissue attached at both commissures and containing the coronary artery, distinctly pulsating when loosened and grasped between two fingers. This flap, when sufficiently mobilized, can be easily brought down with a twist of only 90 degrees and approximated accurately to the flap which has been previously brought into place by any method the surgeon may prefer. Dr. Parham did this in one case with admirable approximation and complete covering with mucous membrane, but unfortunately a mistake in technic, in dissecting too narrow the outer part of the flap in order to bring it down with less strain, resulted in cutting of the coronary artery and the death of part of the flap. This can be avoided by steering widely when approaching the commissures, from the midline of the lip in making the two parallel incisions which mark the width of the flap. It might be supposed that the upper lip would be much damaged, but it is remarkable how little appears to have been removed when the margins of the gap in the upper lip have been accurately approximated. Dr. Parham said that in New Orleans the now well-known Doyen serum was given a rather extended trial in some eight cases. Dr. Doyen furnished enough of the serum for test by a commission to be appointed by him. The results will be given in fuller detail on another occasion, but the conclusions in these cases were absolutely negative.

Dr. E. M. Sala, Rock Island, Ill., reported the case of a man who cut his throat with a razor, cutting through the larynx and esophagus, but missing all the important blood vessels. He was brought to the hospital after having been sutured up on the outside with silk. Forty-eight hours after the first sutures were inserted the entire wound gaped open; it was then sutured with silver wire. These sutures also gave way and they had to deal with an open wound. The man was fed through the neck with a tube for two weeks. He wrote a note, asking if milk was all he was going to have to eat, and was told "yes." He wrote: 'Well, I can take that without the tube." A nurse brought him a pitcher of milk and he doubled his chin close to his chest and drank the entire contents of the pitcher. From this time on the tube was abandoned, and by closing the false opening in the esophagus the man was soon able to eat anything. He remained in the hospital six weeks and the cut opening in the esophagus entirely healed up. He left the hospital with a small external opening in the larynx, which no doubt also healed soon afterward.

Dr. Jacob Frank, Chicago, stated that he had a case similar to Dr. Terry's about five years ago, which he exhibited to the Chicago Medical Society. He operated for cancer of the larynx, removing the larynx and the esophagus. The important point is, that after the operation the patient was able to articulate sufficient to be understood in a room with a seating capacity of 300. There are some other cases on record of a similar nature. The first person to have called the attention of the profession was Dr. Solis-Cohen of Philadelphia. In Dr. Frank's case the operation differed in one respect, as he tried to close the wound, but Dr. Terry did not. It might possibly be that this was the reason for the re-establishment of false vocal glands. He could notice in the granulating of the wound the formation of little bands which took the place of the vocal cords.

Dr. Charles A. Powers, Denver, did not agree with Dr. Rodman that cancer is not liable to develop at the site of leucoplakia of the tongue. He thinks that a patient at or beyond midlife with a persistent lingual leucoplakia is in greater danger of cancer sooner or later than one who has no such lesion.

Dr. Rodman said that it is always a disadvantage to have the hands of the assistant in the way, and he has a scheme for controlling hemorrhage in harelip operations which could very well be employed here. It makes the operation practically bloodless. He said that Dr. Stewart misunderstood him; he said nothing about the removal of the glands. All operations should be supplemented by removal of the glands, and he never operates on the penis without exploring both groins. Dr. McGlannan spoke of pain in mammary cancer, but pain is no more a feature of cancer of the breast in the early stages than it is of an adenoma or a fibroma. That is the reason why early diagnosis is not made more frequently than it is, as people expect there should be pain. It is only when the cancer has become adherent or ulcerating, or both, that there is pain, and if one waits for pain the propitious time for operation has passed. Dr. Rodman agreed with Dr. Rixford that resection of the costal wall may be necessary. He had one such unhappy experience, where he resected a part of the sternum. This is only justified in a small percentage of cases. He did not say that leucoplakia was not followed by cancer of the lip; he said it is not followed by cancer so often as to make it wise to operate in all cases of leucoplakia.

Dr. Grant said that there is no difficulty, by any of the methods in use, in removing all the diseased tissue of lip, cheeks and chin. It is a more serious problem to secure suitable flaps, and to make a good, presentable and useful mouth. If the flaps should, as might happen in all methods, be too broad, it is easily remedied by retrenching the flaps. The hemorrhage in the first stage of the operation, in bad cases, he controls partially by tissue pressure forceps. The posterior blade, long and conical, is thrust through the cheeks or tissues from inside, and clamped to the broad anterior blade. The temporary ligatures suggested by Dr. Rodman are always convenient and useful. Dr. Grant cut both facial arteries in three of the cases reported, and it did not interrupt the satisfactory healing of the wounds. In the upper lip the diseased tissue is excised by same method as the lower, and the triangular flaps are formed by making the incisions from the superior angles of the wound, upward and outward. Only very exceptionally is the upper lip the primary seat of disease. In the usual condition he has an absolutely reliable, fixed point for the flaps in the preservation of the chin tissues, to which the flaps, with a mucous membrane already intact, are secured; and when necessary for enlarging the mouth (to fit loosely the first three fingers of the hand when inserted flat), the operation at the corners of the mouth is ample and gives a ready, easily applied mucous membrane to the vermilion border of the lips. It is better than the procedure of Langenbeck, in which the mucous membrane is taken from the upper lip. In order to make this flap secure it is best to leave the base or stump adherent to the upper lip while adhesion is taking place to the lower. When this has occurred the stump is freed from the upper. This necessitates fixation of both lips in the meantime, and necessarily interferes with feeding the patient, and with cleaning and irrigation of the mouth. A detached flap is never so certain to adhere and heal satisfactorily in this locality; while the operation at the corners of the mouth accomplishes the double purpose of perfecting the size and shape of the mouth, and giving a well nourished, certain covering to the lips, and interferes in no way with the care of the parts and administration of food during the healing process. The suggestion to remove lymphatics with the primary growth *en masse* is impractical in this locality. Neither is it important, as the submaxillary glands, which are the new foci of infection, are promptly extirpated. The *x*-ray was used in all these cases except No. 3, and aggravated the condition in all, causing a more acute inflammatory condition, and, Dr. Grant is satisfied, more rapid extension of the disease. He believes this true in all cases except when the disease is recent and superficial in extent, while after operation it may be useful in preventing recurrence, and for this purpose he advises its postoperative use in all cases. Dr. Grant said that he purposely refrained from discussion of the causation, as he has nothing new to offer. All the patients were inveterate smokers, using the pipe, except the last one, who for twenty years had displaced it with a cigar. Dr. Grant has never doubted the evil influence of persistent irritation as a causative factor in the malignant degeneration of an ulcer, or tissue, originally benign; and he does not think it inconsistent with the existence and influence of a specific cancer germ.

Dr. Terry declared that we need something to urge us to more radical measures. He does not feel discouraged by the condition of the patient which he showed, and still hopes to be able to do something further of value to him, perhaps by resection of the upper part of the sternum.

A PLEA FOR NATIONAL AND LOCAL BOARDS OF SCHOOL HYGIENE.*

ALICE M. SMITH, M.D.
TACOMA, WASH.

The altruistic ideal is the noblest conception of man, and preventive medicine is its most practical application. Thus, altruism is the natural rôle of physicians, in that it is their natural function and their duty to be guardians of the public welfare; to see to the eradication of diseases and their attendant evils; to influence public opinion, public sentiment and public action in all questions pertaining to the health and education of the people, and to make the public familiar with the causes of disease, degeneracy and crime, together with the most important measures for their eradication and prevention.[1]

Science has clearly demonstrated that much of the disease and misery of mankind is avoidable—that disease is a terrible punishment inflicted on the human family for living out of harmony with the laws of health. When one pauses to consider the enormous annual loss to the government and to society through disease; the terrible suffering attended by the temporary or permanent, partial or complete disability of individuals; the tendency to degeneracy and crime in succeeding generations; the deaths, the losses in the business world, due to the serious interruption to business; the money value to the government from the wasted lives that are needlessly sacrificed, it becomes evident that it is the duty of the government to protect its people from these perils—preventable diseases.

Let us consider, briefly, the enormous loss to this government through disease. It is estimated that the minimum value of each wasted life is, at least, one thousand dollars to the government. Professor Osler estimates that of the seventy million people of these United States there are always one million two hundred thousand people afflicted with tuberculosis, out of which number at least one million will die of this disease. Thus the value of lives lost from tuberculosis would be upward of ten billion dollars—and this does not reckon with the physical disabilities that appear in the offspring of parents so afflicted.

Then, too, think of the numerous other preventable diseases which collectively claim a much greater number of victims each year, and some conception will be formed of the appalling loss to the government through disease.

Because of the relation of school hygiene to the science of human development and to preventive medicine, and because of their interrelations with the problems of government and of law, of the business world, of criminology and of sociology, there are no subjects of such vital importance to mankind as the education and hygiene of the developing child.

All through infancy, childhood and youth, there is a struggle for existence, due to the development of the alimentary and other systems. During this time, great strides are made in physical, intellectual and moral growth. It is a period of stress, in which the vital resistance is lowered against the inroads of disease; a time when permanent disability is most likely to be incurred.

Every human adult is a composite result of heredity, prenatal influence, environment and disease. Consequently, because of the unfavorable heredity and home environment of many children, the close connection between their mental and their physical development, and the fact that these children spend a greater part of their waking hours at school—in cities the average school year is two hundred days, in villages one hundred and eighty days—it seems reasonable to impose on the public schools of our country the burden of ameliorating these conditions. Thus, not only does school hygiene become intimately associated with the evolution of the individual, but it seems also to be one of the most important factors in the problem of education and of preventive medicine—indeed, of society itself, since the progress and vigor of nations largely depend on the education and environment of childhood and youth.

For the year ending June 30, 1902, the Commissioner of Education reports that the total enrollment in schools and colleges, public and private, was 17,460,000. Of this number, there were enrolled in public institutes, supported by taxation and funds belonging to states and municipalities, 16,041,016. Moreover, in addition to the enrollment in schools and colleges, as given above, there were pupils enrolled in special institutes, more or less educational and practical in character, 620,840, making a total of 18,080,840. Thus between 20 and 21 per cent. of the entire population and about 72 per cent. of the entire number of persons from 5 to 18 years of age are enrolled in the common schools of our country—all of whom are receiving the education and physical development that shall determine their value to society and to themselves.[2]

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

[1] I have quoted rather extensively from my paper, "A Study of School Hygiene, Development of Children, and preventive Medicine," Amer. Med., Nov. 7, 1903. Again I must acknowledge my indebtedness to the various authorities from whom I have imbibed many of these ideas.

[2] The aggregate of common school property is more than $601,571,307 in 1902, its increase being $25,000,000 over the year 1901. Expenditures for sites, buildings, furniture, etc., $41,758,488, or a percentage of 17.7 per cent. The population for 1905 was 84,000,000.

Each year adds to our knowledge as to the causation of disease. When we think of the homes from which many of the children come—homes which are hotbeds of disease and filth—and that these children bring in their clothing and on their bodies the germs of disease, body vermin, and other insects, we must realize that if all matter rich in pathogenic bacteria and insect dangers probably none can equal or compare with the average dust of school rooms as a source of the preventable ills from which we suffer. Then, too, there are other evils of a faulty school hygiene due to defective heating and ventilation, to overcrowding, to the mechanical irritation to the respiratory apparatus from the dust, or from dirty lavatories, to eye-strain, ear troubles, coryza, catarrh, infectious diseases, postural diseases incident to faulty school furniture and to faulty positions in sitting, writing, studying and standing; all of which may cause avoidable diseases leading to permanent disability, degeneracy, crime, or even to death.

Is it not, then, imperative that a better system of school hygiene be instituted in order that children may receive their "absolute civil rights"—the right of personal security and protection from the government against avoidable evils which cause more or less suffering and permanent injury to their physical or moral health—preventable injuries against which neither parents nor children have any redress; and also that they may receive every opportunity to develop sound minds and sound bodies by means of a school environment, education and physical training that shall minister to their maximum development and place them in right relation toward society?

The defects of the present system are: The ignorance of the average school board of special technical and scientific knowledge as applied to the science of human development and progress; the phenomenal extravagance incident to this ignorance and to so many separate managements; the want of organization; the lack of proper medical supervision of the school hygiene and of the needs of the individual children, and the ignorance of parents and teachers of the requirements of children for their best physical development. Is there not, then, a need of radical reform? To bring about this reform will require long, intelligent and persistent effort on the part of the medical profession, that the public may be made to realize that the individual welfare depends on the general welfare and vice versa, and that no one class can be made to suffer without producing a certain reaction on every other class.

The momentous question, then, becomes: What are the changes essential to the evolution of a better system? They are many and radical. This evolution of a better system implies a practical working ideal very much in advance of the present conditions. There must be an elimination of those elements inimical to the social welfare and such improvements as may be found expedient, if the school ideal is for every child to attain perfectly his maximum development, normal impulses, and such self-control that he may become a useful member of society. It is, then, self-evident that the essential reform needed in the evolution of a better system is the practical application of preventive medicine and that broadly educated physicians must become the chief directors and supervisors of such a system.

If preventive medicine is to assume its legitimate place among the social forces, some method of procedure must be adopted which shall place physicians in authority over these matters. This can only be brought about by organization, local and national. To this end, I would submit suggestions as to the establishment and work of such an organization, leaving the details and perfecting of the system to be worked out by the profession and by the public.

Such a system should be supported by the general government and not by the school fund; therefore, there should be a national board of school hygiene and preventive medicine to be composed of representative, non-partisan physicians, selected because of their general efficiency and knowledge—the commissioner of education and the commissioner of public health, when we have one, as members *ex officio*. It should be the duty of this national board to make investigations in school hygiene, in education in its relation to human development, and into the causes and means of prevention of contagious and infectious diseases and of degeneracy and crime; to indicate measures of national importance in preventive medicine; to frame laws for the protection of the public health; to be the center of information of all matters relating to the development of children, school hygiene and public health; to be an authority on the scientific and sanitary construction of school buildings and school furnishings after the most approved pattern, and to furnish architectural plans and estimates of cost for the construction of these school buildings and their furnishings. It should superintend the civil service examinations of all physicians employed in the various departments of the service, and it should have charge, also, of the examination for school janitors; afterward issuing certificates to the successful candidates for examination; and it should publish circulars and bulletins of information to be distributed by the various departments of the service, etc. The several departments of investigation of such a board should be assisted by advisory boards composed of intelligent and broad-minded men and women, experts in the work of their special department; men and women, in a word, who have attained to success because of their special ability in their own line of work.

A state board of school hygiene and preventive medicine should be established whose duty it should be to supplement the work of the national board. It should supervise the choice of location and the construction of the school buildings of the state on the best hygienic principles and plans outlined by the national board; it should help the national board to frame laws for the protection of school children and the public health, and it should promote the necessary legislation to make them effective in the state; it should have general oversight as to the efficiency of the work of the physicians who hold public offices under this system; it should have the power to close insanitary schools; it should determine the fitness or unfitness of incorrigible children for attendance in the public schools; it should be the final repository of all statistics and records of children after they have left the schools; and it should make a special, careful, systematic classification and study of these records with reference to their sociologic value in the science of human development.

The local board of school hygiene and preventive medicine should be composed of non-partisan and successful business men and physicians, and the municipal commissioner of health, or health officer, should be a member *ex officio*. It should be the duty of this board to supplement the work of the national and state boards; its duties should be such as are ordinarily performed by the school board of the municipality and not otherwise provided for by the state and national boards. It should be the repository of the individual records of all school children while they are enrolled in the public or other schools; and when the children leave school permanently it should forward these records to the state board, where they should be kept on file during the lifetime of the individuals whom they concern. Should the child leave the municipality during school life, his record should be transferred to his new school board of hygiene and preventive medicine.

Another important feature of this system should be the establishment of a complete federation of all boards of school hygiene and preventive medicine in the state with the state board, with the local, state and national boards of health, and with the state and national boards of education. Such a federation should be so perfect in all its details that the work of one board would supplement the work of the other in all matters of common interest; and if for any purpose the school record of any given individual be desired for the department of justice or for scientific research in sociologic problems it should be possible to obtain it on very short notice.

As the education of teachers in the principles of hygiene and preventive medicine must necessarily be very superficial, and as the school age includes the period of greatest development, during which the children must spend a large part of their time in the school buildings, it would seem imperative that if only one principal can be afforded in any school building this individual should be a graduate physician from some reputable medical school. It is certainly to be supposed that the well-qualified teacher is better able to supervise the general education of the child without the constant oversight of the superintendent than to care for its physical needs in accordance with the principles of hygiene and preventive medicine without medical supervision.

The work of a medical principal, apart from the oversight of the general educational work of his teachers and co-operation with the local and state superintendent of schools, would be to keep a vigilant guard over the health of the pupils and thoroughly to examine physically and otherwise every applicant for admission to the school, after which examination the grade, class, exercises, diet, amount of sleep, amount of study, etc., should be prescribed; and, if there should be any disease, malformation or other physical defect present, requiring the services of a physician, the child should be referred to the family physician for treatment, and such treatment should be insisted on as long as need be. It should also be the medical principal's duty to inspect the hygiene of the school building and of the grounds and to supervise the heating and ventilating systems and to control the work of the janitors. He should have the power to close insanitary schools. It should be his duty to report to the local health board officer all pupils who are absent from the school because of contagious diseases, and no pupil absent from such cause should be allowed to return to school without a written permit from him. All private schools should come under these public-school regulations.

There should be some systematic plan followed in making the physical examinations admitting pupils to the schools. The following outline is only suggestive of the scientific possibilities which this work opens up for the promotion of a social ideal through scientific investigation and the application of preventive medicine in the development of children.

Such an examination should ascertain the hereditary data. This should include the nationality, family record and the home environment, and would aid in determining the relative importance of any physical abnormalities found in any individual case. It would also aid in determining the probable reaction to educational influences of those who are naturally weak, backward, degenerate, depraved and criminal. The first physical examination should include the Bertillon system of physical measurements and descriptions, modified and expanded until they best meet the morphologic, physiologic, pathologic and sociologic requirements. This and subsequent examinations should investigate the physical states as to diet, quantity and quality; condition of digestive system; general metabolism; condition of the blood and organs of circulation; condition of excretory organs; the response of the muscular system to dynamic tests; the reaction and reflexes of the nervous system; the physical and neurologic activities, including the physiologic data, which deal with the fundamental elements in the character, morality, education, religion, reason, memory, and the sentimental bias; the relative capacity of the various organs to the physical demands made on them; the pathologic data, which includes the summing up of all the abnormal findings; and the prognosis as to the probable development of the individual along normal or abnormal lines. The fatigue of children at various times during the school day should be registered by means of the ergograph.

There should be a county medical superintendent whose duty it would be to visit the country schools and perform such duties as would devolve on the medical principals and superintendents of city schools. He should also give out literature and printed instructions for the aid and education of the parents, that they might know the best home care to give their children.

Further, to aid this campaign for the maximum development of our school children, it would be necessary to enlist and organize the various social forces to help on the work of preventive medicine. This means education—the education of parents and others as to their responsibilities toward the children and the public.

Club women should be interested in forming health societies and sanitary squads for the inspection and improvement of the neighborhood and home environment of weak, backward, sick, degenerate, incorrigible and vicious children, and to raise funds, that those needing special medical care may be provided with the means for such treatment. There should be efficient factory regulation and inspection regarding minors; and dependent, sick children should be provided with efficient medical, surgical and hospital treatment. So, too, discrimination should be practiced in favor of the nervous, weak or backward child. When children are known to be subjected to constant ill treatment from their parents, measures should be taken to have the parental rights forfeited.

The pamphlets of instructions on home and public hygiene and preventive medicine, treated in a popular manner, issued by a national board of school hygiene and preventive medicine, should be distributed to parents through the medium of the local boards of school hygiene and preventive medicine. Each school should be made a distributing center, from which these pamphlets would be carried by the children to their parents.

There should be printed forms, or circulars of information, on the special hygiene corresponding to the normal development of every period of school life. These periods should be divided into six months or a year each. These circulars should be given, one to each child, according to his age, by the medical examiner, for comments in regard to the care needed in any given case. In this way there could be brought about intelligent co-operation between parents and educators.

Finally, special provision should be made by the state for the separate education of the idiotic, depraved, insane, epileptic and the natural criminal.

There should be industrial homes for the incorrigible, friendless, and homeless girls and boys; a state board of correction and charities; a public school for dependent children; a public school system of compulsory education; and more stringent laws for the protection of the health and lives of children. Such a medical supervision of schools and school children should do away with the closing of schools in epidemics and should be one of the most important measures for checking the spread of contagious diseases. Crime would be diminished, because those children with the stigmata of degeneration and the natural criminal instincts would be discovered early in life and every effort known to science, ethics, and education used to reclaim them. Moreover, those who are subjected to frequent punishment would have justice done them if physical causes were found to be the basis of their various troubles; nervous children would not be forced to practice music or other nerve-racking exercises, tending to the irreparable injury of their nervous systems and general health. So, too, diseases would be discovered in their incipiency and the curable pathologic processes checked or cured, thereby saving many to lives of usefulness.

Such a system of school hygiene and preventive medicine would not only develop the mental, moral and esthetic status of children and transmit a better heredity to posterity, but it would also put physicians in their true professional relation to society and open up a very broad field of usefulness to an overcrowded profession.

DISCUSSION.

Dr. C. F. Wahrer, Fort Madison, Iowa, said that Dr. Smith's paper reminded him of a question that once came from an unknown place: "Cain, where is thy brother Abel?" And the answer was, "Am I my brother's keeper?" Physicians, school teachers, and a good many other people are always trying to do something for the betterment of mankind, even if it does make a strong hit at their financial success. It is a question how much we are responsible for our fellowmen, in how much we are our brother's keeper, and how much we are bound by the ties of humanity to better conditions in general, and how much we can really do. It seems in our law-ridden country, which has so many laws on its statute books, that our laws are increased and modified in various ways, and yet the Utopia of our ideas has not been reached. Legislators usually do nothing they are not compelled to do. The legislator would far rather introduce a river and harbor bill, in which millions are involved, than to see that a thousand or fifteen hundred or two thousand dollars are appropriated for some such schemes as that advanced by Dr. Smith, and he does this because he is importuned to do it. Dr. Wahrer advised adopting the methods used by those who want river and harbor appropriations, or things of that sort, namely, addressing county senators and representatives or the national representatives and senators in Washington. Dr. Wahrer then commended the organization of the profession in the United States, and said that the people must be taught that there are physicians who can do more than sell compounds and make visits at a stated price. He said that the physician must be a factor in the community for morality and for everything that stands for the betterment of mankind.

Dr. A. W. Fairbanks, Boston, agreed with Dr. Smith that there is great opportunity for work in the schools. He belongs to a city that was the first to introduce medical inspection in the schools, and is one of the physicians appointed by the Board of Health for this work. He said that, although there has been medical inspection of schools so long in Boston, the peculiar condition of things is that as yet physicians have little or no control over those features of school life affecting the general health of the child, such as the seating room, the physical exercises, etc. They are required to be on the watch for contagious or infectious diseases and to decide on the attendance or non-attendance of any child so afflicted, and, to a certain extent, have some power of advice as to the attendance of cases of other than contagious affections. As to physicians being principals of schools, Dr. Fairbanks thinks there is too much detail, of a non-medical character, so that the physician would have most of his time taken up with technical details of administration. In regard to the Utopia which Dr. Smith depicts, Dr. Fairbanks thinks the system would be one of great expense, and he could not, in the five or six hours of school work, cover all these details. There are 2,700 children in the schools over which Dr. Fairbanks has jurisdiction, and he finds it very hard to look after the ordinary medical details alone, and he gives a great deal more time to it than he can afford in doing that. In his work, simple as it is, it is sometimes almost an impossibility to gain the co-operation of the family physician. In reply to a question, Dr. Fairbanks said that he is one of the medical inspectors of schools and has a certain school district. There are others who have the inspection of pupils in their districts. He thinks that the physician's power ought to be greatly extended, and that all matters affecting the health of the school child should be under the jurisdiction of the boards of health.

Dr. C. F. Wahrer, Fort Madison, Iowa, in regard to Dr. Smith's remarks about the ignorance of the average school board, said that the remark is not original. He asked how school boards and the laity are ever to be enlightened in regard to the things which physicians wish them to know unless the medical profession undertakes to educate them. He advised each society to have a publication committee composed of five or six members, who would give to the press the consensus of opinion on a given subject and said that in this way the garbled and incorrect statements on medical topics now found in daily papers would give way to plain statements of facts and the public would thus be educated.

Dr. Harriet Garrison, Dixon, Ill., said that in treating of child hygiene one important point which was not brought out is that every physician should educate his immediate families. When Dr. Dixon goes into a family and sees a child needs a certain regimen for his hygienic development, she prescribes it, and gives the necessary instructions for carrying out the treatment. If she meets a girl from one of her families on the street, walking in an unhygienic manner, she asks her to hold her head erect, to throw out her chest and to step out firmly, and calls the attention of the parents to the child's defects. Every physician should be responsible for his own clientele. In this way the laity can be educated, and if physicians do not instruct each family they never will be.

Dr. J. M. McGavin, Portland, Ore., thinks that as we come in contact with the laity we will be more and more surprised how quickly they take up ideas. Dr. McGavin has had some experience with the Chinese here, and in one case in which a child was dying of pneumonia they said: "We want you to get that stuff that blows the air out of their lungs." They meant oxygen. He finds that the Chinese adopt new ideas very quickly. If physicians do their duty they will be astonished at the rapidity with which the laity become educated along sanitary lines.

Dr. Alice M. Smith declared that preventive medicine rather than curative medicine should be the ultimate ideal in practice, and that physicians would lead more entirely successful and useful lives if this system of school hygiene were to be established, because people would so much rather pay to prevent a disease than to pay for its treatment after it becomes incurable. Moreover, Dr. Smith said that in this system the details would not be insurmountable, because the teachers would assume the responsibility of those duties properly belonging to them. Indeed, many teachers are just as enthusiastic and just as anxious to promote the best interests of their pupils as we are. These teachers, under the present system, are often greatly hampered by interference of principals, who insist on some procedures not suited to the best work of the individual teacher. If the school board will gage competent teachers and demand a certain standard of excellence in results, the teachers will naturally adopt the plan best suited to obtain those results. Thus the medical principal would be enabled to devote the greater part of the time to the hygiene of the school. Dr. Smith believes that the system could be made thoroughly practical in its application and that its direct and remote results would be of incalculable financial gain to the profession and to the public.

THE RELATION OF THE WATER SUPPLY TO DISEASES OF THE ISTHMUS.*

D. N. CARPENTER, M.D.
SURGEON, U. S. N.
WASHINGTON, D. C.

The attention of American sanitarians has recently been directed to the Isthmus of Panama, and it was therefore thought of interest to this Section to present the following observations relating to the water supply, also the diseases studied while I was on duty with the U. S. Marines at Obispo and Empire last year.

During the days of the old French canal company the water supply of each section was obtained from the adjacent rivers or streams and pumped into tanks and relay stations to be distributed to the buildings occupied by the French employes. The native quarters were supplied by street hydrants. The official charts indicated the position of each pumping station, tank, and their connections with the liberal network of lead piping. All these had not been in use for years and were found in need of extensive repair. After the missing parts of pumps and pipes had been obtained from the section storehouse, the marines, by several weeks' work, were able to utilize this original means of supply. The ships at Colon provided distilled water for drinking purposes, which was sent to the camps in tank cars, sterilized before filling by steam. The river and rainwater were at first only used for washing and cooking, but eventually all drinking water was supplied by filtering the river water and sterilizing it with the Forbes-Waterhouse field sterilizers. Former employes of the canal company said that rainwater collected from the galvanized iron roofs through broad gutters into tanks and cisterns, was always an important source of potable water. The marines were quite dependent on it for washing and cooking before the river water became available. The several sections along the line, with their native population of Jamaicans, Chinese, Indians and Columbians, rely on rainwater to a great extent for their potable water. Every house has its unique collection of old barrels, tanks, dredge buckets and cans filled with rainwater containing myriads of larvæ and pupæ of the *Culicidæ* and *Stegomyiæ*.

A few springs and wells were found in use in the canal zone and vicinity of the cities. The springs are surface drains and readily contaminated, illustrated at Obispo, where two such springs were condemned for use, having been polluted by a garbage sink and latrine of the camp. The well at Empire, draining a square of houses and stable, was prized for the sparkle and flavor of its water. Needless to add, it showed, on examination, a rich nitrite contamination, and was condemned for the town use when an epidemic of dysentery appeared.

The sanitary condition and water supply of Culebra, as we observed it under the control of the new French company, was probably a good example of these features of each section during the days of the original canal company. It was not surprising to find that several epidemics of yellow fever, smallpox and dysentery had occurred here. The hill at Empire was occupied the year before the arrival of the marines by a battalion of Colombian soldiers and I learned they had many deaths from disease, particularly dysentery. In this connection it is of interest to mention that no deaths occurred among the marines, although for two months there were nearly 1,500 men on the isthmus.

At Obispo the river furnished a liberal supply of muddy water. By qualitative tests it contained an excessive amount of sodium chlorid, calcium and organic matter, probably vegetable, although the drainage from the native shacks along its banks and the river's general use for washing and bathing were sufficient cause for its contamination. The water from the stream at Empire above the pumping station did not indicate contamination by qualitative tests. Samples from several small streams in the vicinity also did not show contamination except lime and vegetable matter. The lake at Culebra during the dry season had considerable chlorid and organic contamination, probably vegetable.

From Obispo to Colon the Chagres river is available as a source of supply. The sample examined did not show contamination. It was not a sparkling water, had a peaty taste, and contained considerable sediment of vegetable residue. Following the river to its head waters near San Juan it was seen how innumerable were the small streams that flowed into it and it could be more readily understood that after a heavy tropical rain this river might become a swollen torrent difficult of control. Along the banks the native villages depend on its supply. Some of the natives have curious superstitions regarding this river water, which they say causes fever and death. Usually the natives trace the beginning of every ailment to bathing.

Another river not far from Panama and available for supply is the Juan Dias. Here we found a sluggish stream, dark and stagnant. Its waters showed only vegetable contamination.

Nearer Panama is the Rio Grande, which crosses the old Spanish road and during the dry season seems hardly more than a swiftly flowing brook. Its waters are clear and sparkling, containing many small trout. Qualitative analysis indicated this water to be the purest of all the samples submitted for examination by the engineer in charge of the canal.

In the interior the villages are usually situated close to one of the many streams. During the dry season the majority of these dry up, and even the mighty Chagres shrinks to a small rivulet flowing through its broad, stony bed. At such times the water is carried a long distance and left inside the shacks for many days. At a certain village where we arrived one night, tired and thirsty after a long ride, we were only too glad to buy a can of such water, and, after boiling, drank of it freely. In the daylight we saw that it was not unlike pea soup in color and consistency. Some of our officers who were in an expedition to Yavisa and Real, far in the mountains, said there were many streams and brooks with pure, cold and sparkling water in that vicinity. During the dry season the tendency of all these Panamanian rivers to vegetable contamination is to be expected when we find the small streams shut in by dense overgrowth, constantly shedding leaves and twigs into the water beneath. For all purposes of water supply in the canal zone it would appear that the Chagres river is the most suitable, but this question must be satisfactorily settled by the chief sanitary officer and the engineer in charge. This problem pertains not only for the canal zone but for the cities of Panama and Colon. The proximity of the Rio Grande to Panama and the excellent quality of its waters suggested, if the quantity was sufficient, its use for a local supply. During the height of the dry season its rate of flow calculated into gallons was said by the engineer in charge to be more than enough for all purposes.

---

* Read in the Section on Hygiene and Sanitary Science of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

The disposal of sewage and garbage and their relation to the water supply will be among the most important questions of the future. The marines depended on field latrines and garbage sinks, but these were considered to be a constant menace. There has never been a sewerage system on the isthmus in connection with the canal sections. Among the natives primitive methods prevail. Solid and liquid refuse are thrown out on the surface of the ground, where the hogs and the buzzards, self-constituted boards of health, devour it. Adjacent woods and bushes serve as privies for the majority of the natives, but a few have outhouses, the condition of which testified in favor of the primitive methods. The French section houses had been provided with stone vaults and earth closets or had used the barrel system. Their garbage and kitchen waste had been led by brick drains some distance from the kitchens or was deposited on the surface at a convenient spot. In the cities of Colon and Panama we saw the same methods. There were also local flushing systems and drains for modern closets and daily collections of garbage. Usually the native houses have a privy vault at the back of a central court-yard or, if an apartment house, this could be used in common by several families. A sewerage system, not only for Colon and Panama, but for the entire canal zone, will undoubtedly be planned and constructed by those who have charge of the future sanitation.[1]

Having control of the water and food supply of the marines and being able to compel obedience to sanitary regulations, it was not surprising that, by comparison, there was little sickness. The results accomplished show more reasonable hope for the future. The principal diseases were malaria and dengue. As our drinking water was beyond suspicion, we therefore looked for other causes of infection. The two cases of dysentery which occurred in camp probably came from the use of town water. One small epidemic among the natives at Empire was believed to be due to the well water previously mentioned. Isolated cases of dysentery were treated at the clinic of natives. Strange to relate, typhoid fever was not seen and even on investigation in the hospitals at Colon and Panama no cases could be found. An American physician practicing in Colon told me that he never had a case of typhoid to treat since he had been on the isthmus, and this statement was repeated by physicians practicing in Panama.

The relation of the water supply to the frequent presence among the natives of intestinal parasites, especially the *Ankylostoma duodenale*, is more apparent. In view of the careless methods for the disposal of excreta, it is readily seen how ova from an infected case could contaminate the adjacent stream, also how epidemics of dysentery had spread, and how easy it would be for a disease like cholera to sweep over the isthmus, as it did in the early fifties.

There was no other disease treated which could be directly traced to the water supply, but indirectly the present system of allowing the natives to collect water in open receptacles about their dwellings causes disease by acting as breeding places for mosquitoes which transmit malaria, filariasis or yellow fever. By noting the location of each case of malaria among the marines, it was demonstrated in both regiments that the greatest number occurred in the company houses nearest to the native dwellings, on the outskirts of the camp. A noticeable decrease in cases was observed when the natives were forced to vacate their dwellings. The supposed immunity of the native from malaria is probably due to repeated attacks in childhood. From among the children treated, examination of the blood revealed the parasite constantly in those varying from 6 weeks of age to 15 years. Such children are a constant menace to the community. The cause of the so-called "banana-belly" in native children was found to be either an enlarged spleen from malaria or due to the *Ascaris lumbricoides*.

Many patients who came to be treated for dysentery were found to have ova of the *Ankylostoma duodenale* in their dejecta. The Indians and the Colombians, both young and old, are the greatest sufferers. When diarrhea was not complained of and the blood was being examined for a supposed malarial infection, the diagnosis of hook-worm disease was frequently made by the eosinophilia and hemoglobinemia.

Filariasis was not common. One case of recurrent lymphangitis failed to reveal filaria in the blood taken after 8 p. m., but there was decided elephantiasis of the affected leg. Three other cases of elephantiasis were seen.

It has been definitely proved that the transmission of malaria is through the agency of the anopheles mosquito and not due to drinking water or miasmatic influences. Additional proof of this was given among marines who, while using distilled water, continued to be infected with malaria. Our ignorance of the isthmian fevers caused us from the first carefully to study and tabulate each case in order to differentiate and throw some light on this so-called Chagres fever. Malaria was recognized by the parasites in the blood. The presence of another fever with symptoms resembling malaria, but without parasites in the blood, was suspected. This was dismissed on differential diagnosis. It was believed that they were cases of malaria without the parasite being found. At the beginning of the rainy season such cases became frequent, and it was soon evident that we had a dengue epidemic.

It is important to emphasize the difficulty of diagnosis between malaria and dengue. It is also believed some dengue cases would be difficult to differentiate from yellow fever. Examination of stained specimens of the blood proved to be the surest method for differential diagnosis between malaria and dengue. There were a few cases necessitating a long search or repeated examinations. Quinin was not given until the parasite was found. There is no question of it being the safest antipyretic for use in the tropics if blood examinations can not be made. In dengue it was found apparently to have no effect on the typical fever, and in a few cases it evidently increased the symptoms of cerebral congestion.

Many authorities state that examination of fresh specimens of blood are most reliable. Stephens and Christopher insist on stained specimens, and the conclusion we reached agreed with them. Fresh specimens proved to be misleading, for it was found that in the blood of these dengue cases there were irregularly shaped, brownish-yellow, intracorpuscular forms, often seen in shrunken brassy corpuscles, appearing not unlike estivo-malaria parasites. Some of these resembled the *Piroplasma bigeminum,* and may be the blood parasite described by Graham of Beyreuth. They also resemble artifacts which occur in normal blood as it dries. Their presence in the fresh specimens was thought by us to be due to necrobiotic changes in the corpuscle, possibly from a toxin in the blood. We reached this conclusion when in 45 cases of dengue the blood counts indicated no destruction of the corpuscles. In fact, there was more often a polycythemia. Moreover, these piroplasma forms did not appear in the stained specimens. Finally, by feeding experiments with several species of virgin mosquitoes and after varying intervals of time examining the stomach and salivary glands, these piroplasma forms were not found. We also conducted several inoculation experiments by virgin mosquitoes fed on dengue cases at various stages of the disease. The details of these experiments, tables of blood counts and urine examinations, have already appeared in The Journal A. M. A., Jan. 21, 1905.

---

[1] Since this paper was written I have been informed that the city of Panama is being supplied with water led by pipes from a lake or reservoir near Culebra. A standpipe at Ancon is to be built. A sewerage system has also begun at Panama.

During epidemics, when there are many blood specimens to examine, the stained preparations are easier to make than fresh specimens. The technic used was simple: A damp rag to cleanse the ear, a quick needle jab, a large drop of blood on the edge of a cigarette paper, and this applied to one end of a clean glass slide, where it spreads out by capillary attraction, after which it is slowly drawn the length of the slide. After the film is dried, 10 or 15 drops of Wright's stain are added, remaining 20 to 30 seconds. An equal amount of water is then added and the specimen stained 3 minutes. The slide is then washed and dried. It can be examined at once or put aside until convenient. Such a smear contains 5 to 10 times the number of corpuscles in a fresh preparation and is therefore equal to that many specimens. It is moreover available for a differential count of the leucocytes. The distinctive staining of the malaria parasite at once arrests the eye and there can be no danger of confusion if we keep in mind for young forms, first, the red chromatin nucleus; second, the vacuole, and, third, the blue protoplasm. Everything else must be excluded. Adult segmenting forms, rosettes, and presegmenting forms cause no trouble.

During the first rise of fever in dengue the blood fairly spurts from the pricked ear, but during the second rise and convalescence it flows sluggishly, coagulates quickly, and is dark and thick. The series of cases selected for blood count indicate that dengue is one of the few fevers with leucopenia. During the course of the disease the differential count of the white corpuscles shows a gradual decrease of the polymorphonuclear neutrophiles and a corresponding increase of the small mononuclear lymphocytes. This by contrast with malaria in which there is no leucopenia and generally a large mononuclear lynphocytocis, furnished us a valuable aid in diagnosis when the malaria parasite was not found. It takes but little more time when examining a specimen to record its differential count and estimate the number of leucocytes. To recapitulate: Evidence of leucopenia, a normal differential count, and no malarial parasites are in favor of the first rise of fever in dengue. If a malarial blood in which no parasites can be found there will be no leucopenia and the differential count will probably show a lymphocytosis of the large mononuclear and transitional lymphocytes. If there is leucopenia and a decided lymphocytosis of the small mononuclear lymphocytes it points to the second rise of fever in dengue or convalescence.

We investigated other causes of our dengue fever. This disease did not prevail as an epidemic on the isthmus except at our camp. We noted that a number of cases had catarrhal symptoms of the respiratory tract. The increase of dengue at the beginning of the rainy season and a decided fluctuation in the number of cases coincident with dry or rainy days pointed to a direct relation. Our explanation of this was that on rainy days all doors and windows were closed and the houses being overcrowded became poorly ventilated. This would tend to lower the resistance of the mucous membrane of the respiratory tract and favor infection by virulent bacteria. Working on this hypothesis measures to relieve overcrowding were recommended and immediately improvement was observed. Our conclusions were, therefore, that this epidemic was due to a contagious, congestive fever with catarrhal symptoms of the gastro-intestinal and respiratory tract. It resembled influenza in the selective influence of the toxin on the nervous system, in the leucopenia of the blood and also we believe by the possibility of contagion through the respiratory tract. The enlargement of the cervical and inguinal glands in many cases, suggested invasion of the body through the lymphatics. The leucopenia and increasing lymphocytosis might be explained by such infection.

Some of the cases of malaria were of unusual interest. One man had eight attacks of quotidian fever, constantly showing numerous small estivo rings (1/7 diameter corpuscles). He then had a typical attack of dengue with a characteristic chart and not a parasite to be found in the blood. Next he had an attack of fever with a tertian chart and typical tertian parasites in the blood, evidently a superimposed malarial infection, and finally another attack of quotidian fever with the reappearance of the tiny estivo rings. Many of the malarial cases had attacks of dengue and during such attacks the malarial parasite could not be found in the blood. Several cases of malaria were evidently pure infections by the subtertian estivo parasite and the charts were typical of that type of malarial fever. Single and double tertian infections were the predominating malarial fevers with almost the same number of estivo infections. Crescents were rarely seen in these latter cases. No quartan malaria occurred.

The majority of dengue charts are characteristic of that disease, consisting of a fall by lysis in from three to five days from the initial rise and then a secondary rise. A few of the cases would only have the secondary fever on admission. There were two cases, classed with the dengue cases, which had irregular fever charts and considerable albumin (0.125 to 0.5 per cent.). These might have been called yellow fever in the presence of an epidemic.

In concluding this paper the following analysis of symptoms as they occurred in the dengue cases may be of help to us as sanitarians. The eruption, when present, varied from a faint erythema to a profuse measles-like rash. It would often appear with the primary fever. A few cases had an urticarial or purpuric rash and suggested the dengue eruption to be a disturbance of the vasomotor nerves. The eruption was absent or not discovered in many cases otherwise typical. Desquamation was only observed in two cases. A marked congestion of the eyes and face was usual, but also observed in some of the malarial cases, especially in first attacks. Severe neuralgic pains in head, back and limbs, complained of so bitterly by the dengue patients, were described by patients with malaria, but those who had had both diseases said that the dengue pains were more intense and different in character. A peculiar pain on moving the eyeballs, especially when looking up, with tenderness to pressure, is almost diagnostic, yet a few cases of malaria had this symptom. The onset of fever was usually sudden, but in malaria more gradual. Diarrhea and gastrointestinal irritation were particularly noticeable at the beginning of the epidemic of dengue. A few complained of chills, but the majority had merely chilly sensations. Definite chills were common in malaria. Anorexia and vomiting occurred in both diseases. In one case of typical dengue there was fresh blood in the vomitus. Bleeding gums were noted in many. The scleræ looked muddy and in an insufficient light might be easily called icteric. In a few of the cases of malaria there was decided icteric scleræ and jaundiced skin. Such cases were carefully watched in the view of the constant expectation of yellow fever.

Pains in the joints, especially the knees, were occasionally noted, but there was no evidence of swelling. Pain in the epigastrium was commonly complained of in dengue, and over the spleen and liver by those who had malaria. Parasthesias, loss of sensation and numbness of the extremities, increased or diminished patellar reflexes, neuralgic pains in the shoulders, back of neck and chest, muscular cramp, substernal oppression with a sense of suffocation, tachycardia, and even a feeling of impending death were some of the nervous manifestations. Insomnia was common and restless sleep with horrible dreams, mental uneasiness, vertigo, photophobia and frontal headache indicated a decided cerebral irritation. Indefinite neuralgias and loss of power in the legs were seen in few cases and had to be differentiated from beriberi, which exists on the isthmus.

The pulse usually followed the fever, but in the more severe cases during the second rise of fever it was slow to respond. In one case there was an actual divergence of pulse and temperature, an important symptom of yellow fever. At first the pulse was full and strong, often dicrotic, later it became soft and weak. Profuse sweats were common in both malaria and dengue. During the first rise of fever in dengue the skin had a peculiar dry, congested feeling. Herpes of the lips, eyelids, and neck were noted. The tongue was usually dry, with a brownish white coat at the base and a clean tip and sides. In malaria it was swollen and white. The spleen in some, but not all cases of malaria was tender and palpable. This symptom was present in dengue cases who had had malaria. Epistaxis was noted in three cases. In a few of the dengue cases who had diarrhea, blood, pus, and mucus were found in the feces and caused anxiety as to the possibility of dysentery. This condition quickly disappeared.

Among all the 279 cases of fever which were tabulated and analyzed there is, of course, a possibility of there being mild yellow fever. The two cases mentioned as having atypical dengue charts with excessive albumin, one of which presenting a diverging pulse and temperature curve, were decidedly suspicious. It is believed, however, that all were due to either malarial infection or dengue. The chief sanitary officer of the canal, Dr. Gorgas, who kindly examined the data and charts of these cases, did not think that we had had yellow fever.

In closing, I wish to express my indebtedness in collection of data and assistance in blood examinations to Assistant-Surgeon Richard L. Sutton, U. S. Navy, who was associated with me at Empire.

DISCUSSION.

Dr. Denslow Lewis, Chicago, said that the first and most important subject that has to be considered in this connection is the sanitation of the Isthmus, and that we are fortunate in having on the ground so competent a medical officer as Dr. Gorgas.

Dr. Carpenter said that we can feel that the future is safe in the hands of Dr. Gorgas. He has been very energetic recently, but Dr. Carpenter understands at present that yellow fever is now generalized on the Isthmus. Quite a number of non-immunes were sent down a little before the country was prepared for them, and in consequence there seems to have been a generalized infection. He thinks that the success of the sanitary authorities rested on the fact that they were able to enforce obedience to sanitary regulations among men under military control, and it seems to him that if in the future the Isthmus is placed in a sanitary condition, the engineers and employes living under proper conditions could get along very well. The same means for destruction of stegomyia mosquito larvæ will do away with malaria also. Dr. Carpenter thinks this is of great importance, and Dr. Gorgas, he believes, recognizes the menace, so far as malaria is concerned, from the antives. The natives in the vicinity of the camp were forced to move from their houses. This cause was very evident; plans were drawn of every company house and the cases were tabulated and in this way it was found where the greater number of cases were occurring. Everything at first was in the dark. The native physicians gave no light. Of the so-called Chagres fever little was known. Dr. Carpenter thinks that malaria when it is recognized early and is properly treated, is not particularly dangerous. The Marine-Hospital surgeons had no fatal illness among their patients. There were the benign, the tertian and the pernicious infection. Dr. Carpenter was also particularly interested in being able to differentiate in a few cases between the quotidian estivo-autumnal and the subtertian estivo-malaria. The Italians differentiate between these, but he does not think Americans have generally accepted this classification. In reply to a question, Dr. Carpenter said that he did not know how the sewage is being disposed of. He has not been in communication with the physicians on the Isthmus. He heard that they have started to dig up the streets to put in a sewer system for the city.

THE NASAL SEPTUM; A DESCRIPTION OF THE AUTHOR'S PRESENT MANNER OF PERFORMING THE WINDOW-RESECTION FOR DEFLECTIONS.*

OTTO T. FREER, M.D.,

CHICAGO.

TYPES OF DEFLECTION.

The mucous membrane incisions in my method of performing the submucous or window resection vary with the type of deflection and for this reason I precede the details of the operation with a description of deflections as I have seen them, employing for them as much as possible the names in common use and grouping them according to their form.

Angular Deflections.—The double-angled deflection: This variety of deviation I have found by far the commonest. It possesses a vertical and horizontal angle, joining near the base of the septum and forming a projection on the convex side not unlike the corner of a box. The vertical angle (Fig. 1) occupies the quadrangular cartilage and ascends to a varying degree, sometimes into the perpendicular plate of the ethmoid bone. The vertical angle may jut out so strongly that it presses into the inferior turbinated body. The horizontal angle in the usual type of double-angled deflection begins in the cartilage in front of the vertical one *and extends backward and upward in the form of a wedge* into the bony septum, its apex following the superior border of the vomer in most cases, the crista nasalis inferior and vomer curving outwards above the nasal floor to make the lower plane of the horizontal wedge. (Fig. 2.*b*.)

---

* Read in the Section on Laryngology and Otology of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

On the concave side of the deflection a deep trough with a V-shaped bottom is seen ascending backward and slightly upward and corresponding to the projection of the horizontal angle on the convex side. The site of the vertical angle is usually merely indicated by a gentle depression easily overlooked.

The Crestlike Angular Deflections with a Single Angle.—This variety of deflection I have found next in frequency to the double-angled kind and it is distinguished from the latter by the absence of a vertical angle, the horizontal one alone existing. (Fig. 3). It is this type of deflection that is so commonly designated a "ledge, crest, exostosis or spur" under the supposition that it is entirely or mainly a solid projection with little or no concavity to correspond to it on the other side of the septum. The skeletonizing of the deflected *septum incident to the window resection soon showed me* the rarity of massive prominences arising from a plane septum and *I found that the supposed ledges or crests* which I used to saw away were really merely the *summits of evenly hollowed deflections in cartilage and* bone.

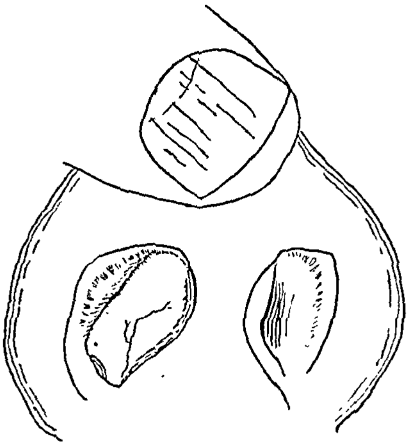

Fig. 1. Deflection in right naris showing vertical angle. From life.

The posterior part of the horizontal angle of deflection may often be seen by posterior rhinoscopy as shown in Fig. 4*a*.

Sigmoid Deflections.—This type, in my experience, is third in frequency, being comparatively rare. The septum may be S-shaped horizontally or vertically. In the horizontal variety the anterior part of the deflection presents a vertical angle or bend like that found in the double-angled deflections, but the posterior, hidden plane of this vertical angle is unusually long so that it crosses the median line and creates behind the first bend a second vertical angle of deflection, usually partly or wholly in the bony septum, and with its convexity in the other naris.

In vertical S-shaped deflections two bends exist with their concavities reversed and situated, *one above the* other, the lower one having the usual form of the crest-shaped horizontal angle, while the upper one is *commonly more gently curved and extends high up into the* perpendicular plate.

Bowed or C-Shaped Deflections.—I have met with very few of these. They are usually extreme, situated *far in front* and *obliterate the naris* by an even bulging of the cartilaginous septum against the outer nasal wall. Posteriorly, however, they merge into the standard type of the crest-shaped horizontal angle.

The bulging cartilage bellies out both vertically and horizontally in the form of a capital C.

Columnar Cartilage.—The dislocation of the anterior inferior border of the quadrangular cartilage (so-called columnar cartilage), from its normal seat above the cutaneous septum is in my experience a frequent complication of all kinds of anterior deflections. Normally the free border of the cartilaginous septum extends in the median line upward and forward above the cutaneous septum from the inferior nasal spine to the space between the median plates of the alar cartilages. In the anomaly mentioned the inferior and anterior angles of the cartilage of the septum are dislocated from their positions above the crista incisiva and between the alar cartilages so that the lower anterior movable part of the cartilaginous septum is displaced from its place above the cutaneous septum into one or the other nostril. In addition, when it is thus freed from its sustaining points, it usually grows downward and forward unrestrained, curling on itself, often creating a decided obstacle in the nostril of the concavity of the deflection it complicates, and appearing as a white elastic object under the skin beside the septum cutaneum. (Fig. 5*a*.)

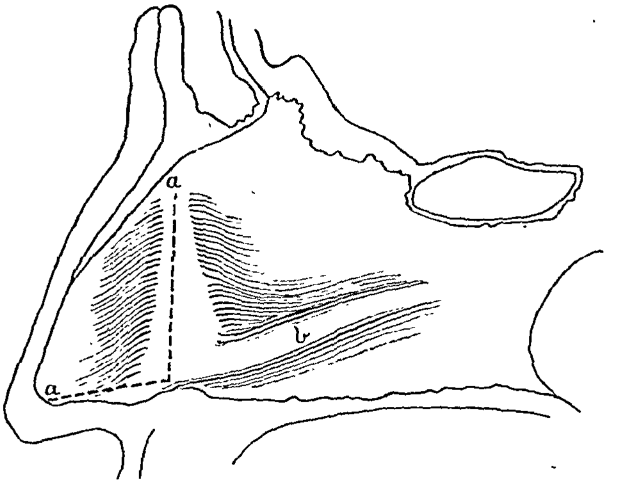

Fig. 2.—Lateral view of convexity of double-angled deflection; *aa*, outline of mucous-membrane incision; *b*, horizontal angle of deflection.

Irregular Deflections.—Some deflections are of such an odd shape that they can not be classified, but the great majority of those I have seen fit into one of the above groups.

Bony Deviations.—Deflections confined to the bony septum are fairly frequent. They are apt to be taken for solid crests or spurs, their projecting portion being sawed away, while the greater part remains behind and continues to obstruct the naris. The window resection extirpates these obstacles radically.

DESCRIPTION OF THE OPERATION.

Preparations.—The operation is to be done, as far as possible, according to the rules of aseptic surgery, a knowledge of which is presupposed. A special operating room is not required, and the resection may be performed in the physician's office.

It is necessary to clip away all of the hairs in the nasal vestibule. They retain dirt, catch the light and even a few of them surprisingly obstruct the view.

Position of the Patient.—Preparations should be made for conducting the operation with the patient either in the sitting or recumbent postures, for both positions have their advantages and it may be needful to change the patient from one to the other while the work progresses. For the operation with the patient reclining I employ a high operating table, one end of which may be raised in order to lift the patient's head to the required level.

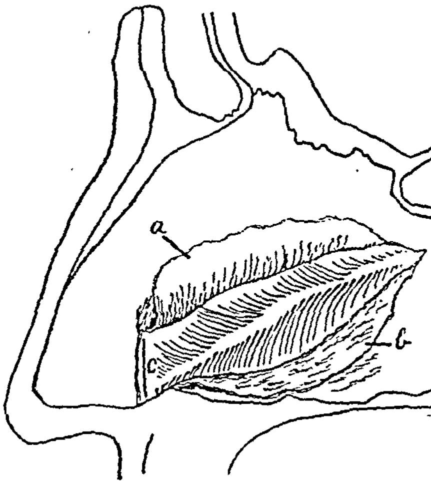

Fig. 3. Lateral view of convexity of crest-shaped deflection beginning well in front: *a*, superior flap: *b*, mucous-membrane pouch formed below; *c*, first cut through cartilage in front of deflection.

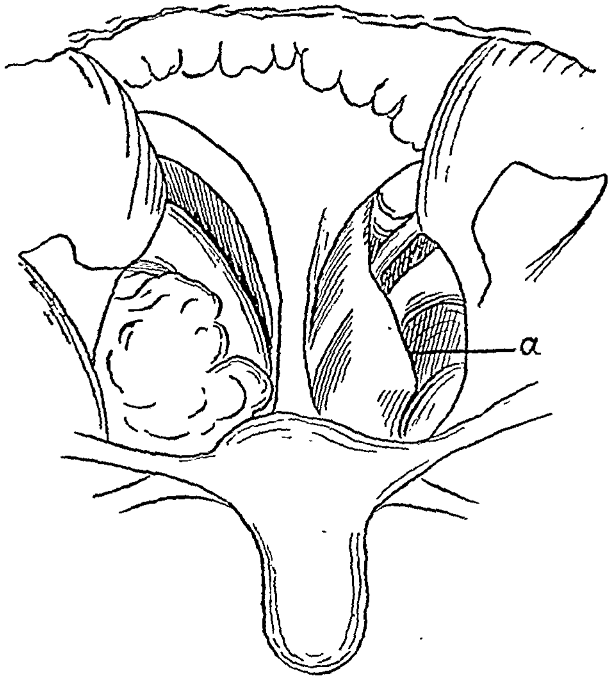

Fig. 4. Posterior view of a bony deflection. From life; *a*, deflection.

Where the recumbent position is employed, the patient avoids the spells of faintness that are apt to attack him if he sits during the operation. Neither he nor the surgeon are fatigued by long-continued sitting in a strained position. What little blood escapes the swabs flows backward into the nasopharynx and is swallowed, leaving the operative field clear. The higher parts of the septum are more easily reached than when the patient sits up, and the assistant who wipes away the blood has a better view of the field.

The advantages of the sitting position for the patient are these: The resection of bony deflections is usually easier than when he lies down, especially where the crista nasalis inferior (synonyms: superior maxillary crest, crista incisiva) and the lower part of the vomer need cutting or chiseling away, for while the upper parts of the septum are most readily reached when the patient is recumbent the parts nearer the nasal floor are most accessible when his head is held upright. The tampon can also be more accurately built up in the latter position. In most cases I begin the operation with the patient lying down and have him sit up at the end to finish the bony resection and insert the tampon. The tendency to faint seldom lasts beyond the cartilaginous resection.

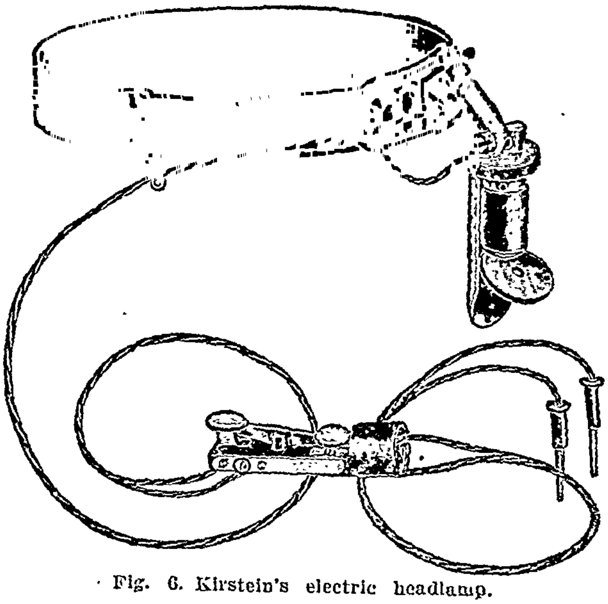

Fig. 6. Kirstein's electric headlamp.

Lights Employed.—The Kirstein electric headlamp (Fig. 6) is, in my experience, the one best suited for the operation. In the usual types of electric headlamps the rays are directly emitted from a light on the forehead, so that the light beams form an angle with the axis of the observer's eyeball, and if a cavity be inspected it is not lighted deeper than the apex of this angle, and for this reason, no matter how brilliant be such a light, it only illuminates the anterior parts of the nasal fossa, leaving its deeper parts in darkness. In the Kirstein light, called by its inventor *das leuchtende Auge* (the shining eye), the light is condensed from above on a small mirror fitted with a central perforation through which the observer looks and which gives him the advantage offered by the common head mirror, namely, that the rays returning to the eye from the illuminated object are parallel to those emitted by the light, and hence the cavity inspected is lighted clear to its bottom. The advantage of the Kirstein light over the head mirror is independence from a source of light for reflection, for this light dazzles the observer and compels him to hold his head in a fixed position relative to the light in order to catch its rays, while the assistants have to be careful to avoid getting between light and operator, and hence are limited in their freedom of motion. Some operators have complained to me that the Kirstein light was not bright enough. In these instances it is not the lamp that is at fault, but the kind of rheostat employed, as many of these do not let enough current pass through them to make the Kirstein light glow brilliantly, although they have ample

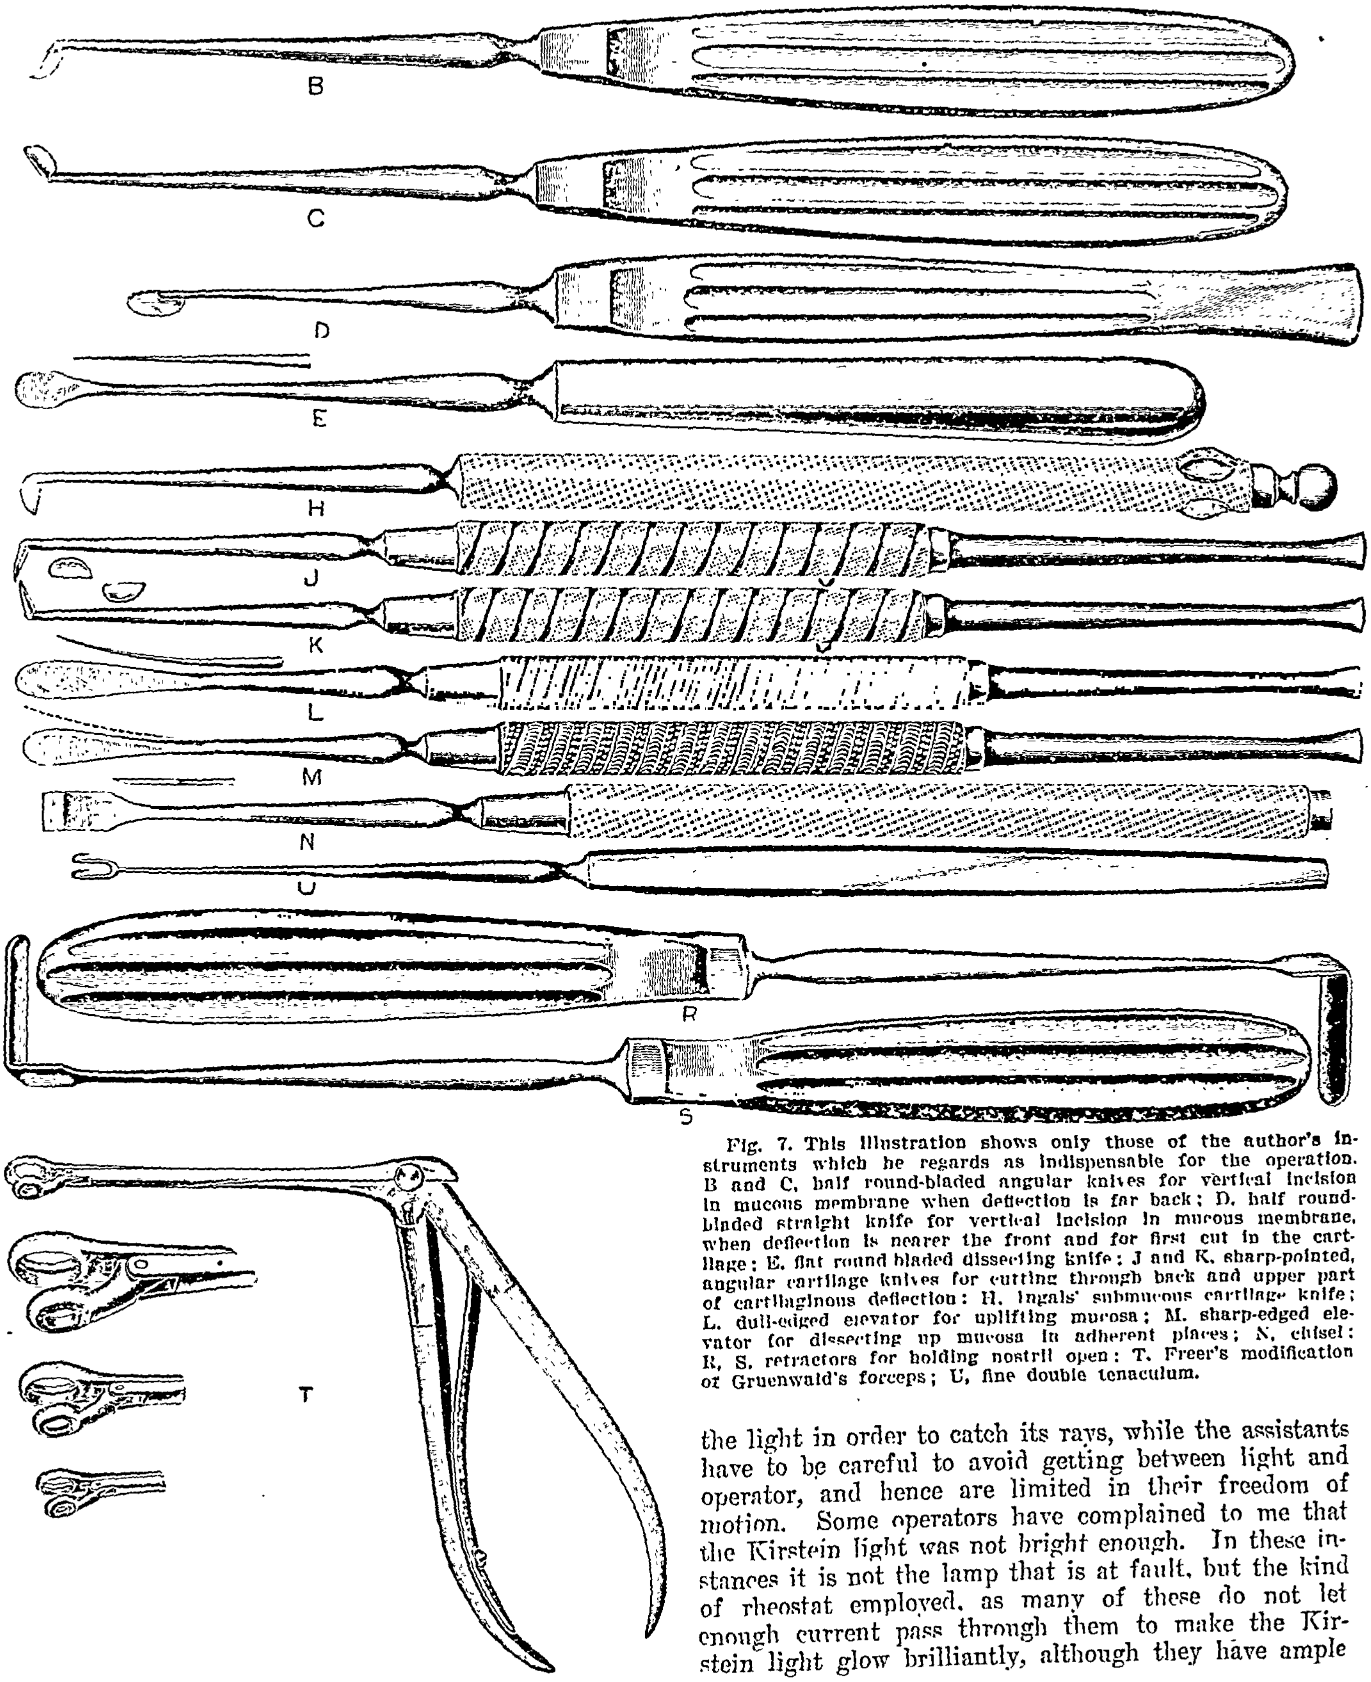

Fig. 7. This illustration shows only those of the author's instruments which he regards as indispensable for the operation. B and C, half round-bladed angular knives for vertical incision in mucous membrane when deflection is far back; D, half round-bladed straight knife for vertical incision in mucous membrane, when deflection is nearer the front and for first cut in the cartilage; E, flat round bladed dissecting knife; J and K, sharp-pointed, angular cartilage knives for cutting through back and upper part of cartilaginous deflection; H, Ingals' submucous cartilage knife; L, dull-edged elevator for uplifting mucosa; M, sharp-edged elevator for dissecting up mucosa in adherent places; N, chisel; R, S, retractors for holding nostril open; T, Freer's modification of Gruenwald's forceps; U, fine double tenaculum.

capacity for the little diagnostic lamps in common use. The regular German Kirstein miniature lamps require from 10 to 12 volts and often an ampere of current to make them blaze with a white light. The O. C. rheostat with a 50 candle power light in series or a small 12-volt storage battery fitted with a rheostat will furnish the required current. Of late I have used 6-volt American miniature lamps in my Kirstein sockets and have obtained as bright a light as with the larger German ones.

Those who prefer the head mirror can use it when the patient lies down if a 50 candle power, stereopticon, pigtail filament, 110-volt, Edison incandescent lamp be used as a light to reflect from. It may be clamped for this purpose to an *x*-ray stand placed beside the patient.

Anesthesia.—In the exceptional cases where the dislocation of the anterior inferior unattached border of the cartilage of the septum from its seat above the cutaneous septum demands the beginning of the resection from a cut along this free border, a 2 per cent. solution of cocain is injected submucously on each side of it, for the thick epithelium over the foremost, lowest part of the septum hinders absorption from the surface. In all other cases, as formerly, I first swab adrenalin, 1 to 1,000, on both sides of the septum to the limits of the deflection, following it in about three minutes with pure cocain in flakes or powder, rubbed on the same regions with a minute, moist swab. The concentration of the drug produces profound local insensibility, which is confined to the operative field and is so rapid that the first cut may be made in about five minutes after the application. I have never seen noteworthy cocain intoxication, though, as the operation proceeds, the pure drug is repeatedly applied to the wound surfaces to maintain the anesthesia and as a hemostatic. The insensibility to pain obtained with pure cocain is so perfect that observers of my operations have been struck by it and have contrasted it favorably with the local anesthesia produced by the usual solutions. I can see no reason for submucous injections of the drug except in the locality mentioned.

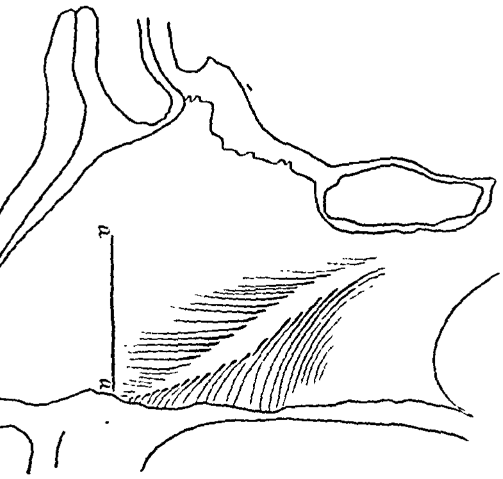

Fig. 8. Lateral view of a crest-shaped deflection beginning deeper in the naris: *aa*, vertical mucous-membrane incision made in front of deflection.

For children I combine chloroform narcosis with the application of cocain. Just enough chloroform is used to keep the child unconscious of its surroundings. As a rule, hardly a half narcosis is needed.

Assistance.—An attendant is needed to hold the nostril open with retractors, and it is well to have a second one keep the field of operation dry by swabbing, as this makes the operation much more rapid and precise. At least 60 swabs rolled on pointed applicators should be ready.

Specula.—No speculum is used during the operation, the naris being held open by an attendant with the flat retractors shown in *Fig. 7* (R. S.), one being broad and the other narrow. They can be adjusted much more accurately than a speculum to suit the varying needs of the progress of the operation.

Incisions in the Mucous Membrane.—These vary according to the type of the deflection. For the frequent double-angled deflections described, my present incision is made in the shape of a capital L looking backward, the vertical cut, as of old, following the angle of the vertical deflection and beginning high up on the septum above the deviation, the horizontal cut extending forward from the bottom of the vertical one along the crest of the horizontal deflection, if it be acute and project greatly. If it be little pronounced, the incision is made along the nasal floor. The cut should extend to the very front of the septum in most cases (Fig. 2). This outlines an anterior flap with its base forward. The posterior extension of the horizontal cut, which gave the older incisions the form of an inverted T, I no longer use. The reason for usually making the horizontal cut along the crest of acute-angled horizontal deflections and not along their base is the frequently great adherence of the mucosa at the apex of such horizontal deflections and below it, so that its separation from below is difficult, and it is better to dissect it off downward from an incision made along the crest.

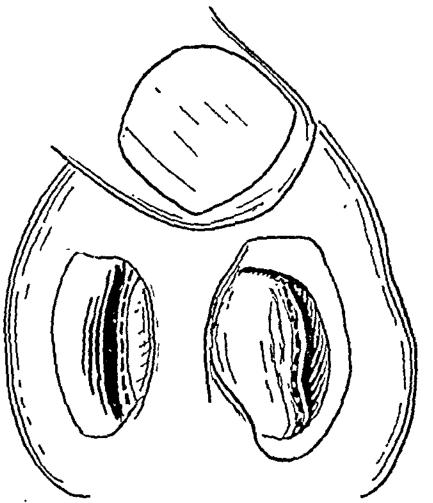

Fig. 9. Deflection showing vertical angle in left naris and dislocation of free border of cartilage into naris of concavity. Dotted lines show sites of mucous-membrane incisions.

The incision for the crestlike deflections varies with their depth in the naris. For those extending to the front of the nostril an incision is made from behind forward along the whole length of the crest of the deflection, curving the cut upward at the front. This outlines a superior instead of an anterior flap (Fig. 3).

Most of the crestlike deflections, in my experience, begin far back in the naris in or near the bony septum, and for these a single vertical incision (Fig. 8, aa), reaching from the nasal floor high up on the septum, is made just in front of the beginning of the deflection and the resection is conducted for this, for in this type of deviation there is no deflection to remove from the front of the naris, and the vertical incision opens the way at once to the deep-seated deviation in the bone.

The mucous membrane cuts are made with the knives with half-rounded edged or round edged blades (Fig. 7, B, C, D, E), B and C being used for vertical angles occurring far back. The surgeon must be sure to make his cut deep enough to sever the perichondrium, so that it can be elevated from the subjacent cartilage, for while the perichondrium usually peels very readily from the cartilage it is only possible to separate the mucosa from the perichondrium by tedious dissection.

Where the anterior inferior free border of the septum is displaced into the naris of the concavity sufficiently to obstruct breathing, causing the anterior plane of the vertical angle of deflection to lie across both nostrils (Fig. 9), the resection is commenced by an incision on the free border of the septum on the concave side, and as much of the deflection is dissected out from this as can be reached. If the deviation extend far back into the bone the usual vertical cut is made along the vertical angle on the side of the convexity and the dissection continued from this.

The horizontally sigmoid deflections require no special incision, and I extirpate them from the usual reversed L cut mentioned for double-angled deviations, the second, deep-seated bend being readily reached from this. The same cut also answers for the C-shaped deflections, the vertical incision being made along the most bulging part of the bend. The upper bend in the vertically sigmoid deflections can readily be reached from the incisions described for the crest-shaped or double-angled deflections.

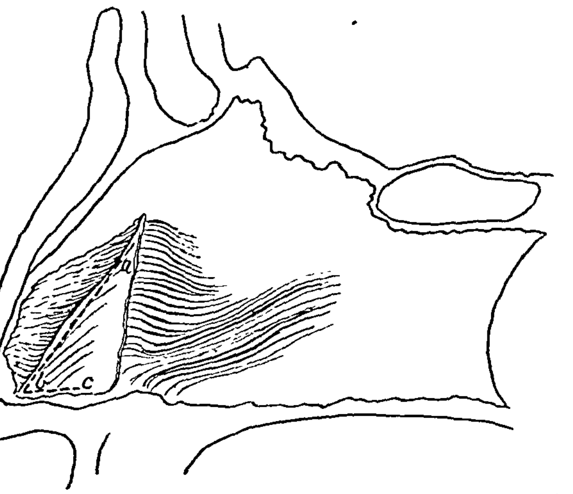

Fig. 10.—Lateral view of septum with double-angled deflection, anterior flap reflected; *abc*, first cut through cartilage.

The Reason for the Incisions Described.—The great majority of deflections have a vertical angle or summit, and the principle of my method in these cases is to begin the separation of the mucosa perichondrium from a cut following this summit. In distinction to this the German operators and their many pupils in America make the first mucous membrane incision in front of the beginning of all deflections, sometimes, as Hajek and Menzel do, at the very front of the septum, on the free border of the cartilage, starting the resection from this foremost part, no matter how far behind it the deflection may commence.

The first part of the separation of the mucosa of the convexity is made easier by the German type of incision, and the single slitlike wound left after the resection is completed closes itself, while my flaps have to be applied and held in place with the tampon. The disadvantage of the German cut, however, is that one has to operate through a button-hole incision far in front and that even the remotest parts of the deviation have to be reached through this contracted orifice at the greatest distance from them on the septum. It is also admitted by advocates of this method that they find it difficult to elevate the mucosa-perichondrium over and behind the vertical angle of deflection and that a perforation of the mucosa of the convexity is apt to occur in this locality. In short, one has the difficulty of conducting the resection in a long pouch of mucous membrane extending back from the very front of the septum and entered from a button-hole incision. This suffices very well for many of the purely cartilaginous deflections, but in the majority of cases there is a bony deviation to resect, extending frequently nearly to the posterior border of the vomer, and until the cartilaginous deviation is cleared away it is often impossible to tell how much bone will need removal. To judge from my own experience with the difficulty of resecting the bony deflection from the button-hole incision, those who use this method must often slight the bony part of the operation. In fact, one gains the impression from their writings that the main thing is to resect the cartilage and that bony deflections are an unimportant complication, whereas in my experience I have often had to cut away as much bone as cartilage to free the nostril.

In distinction to the German methods my vertical incision leaves but a short, widely open sac of mucous membrane behind the vertical angle, and the latter does not have to be passed in elevating the mucosa of the convexity behind it, as its liberation begins on the apex of the angle. In addition the bony part of the deflection is made perfectly accessible and is exposed to view.

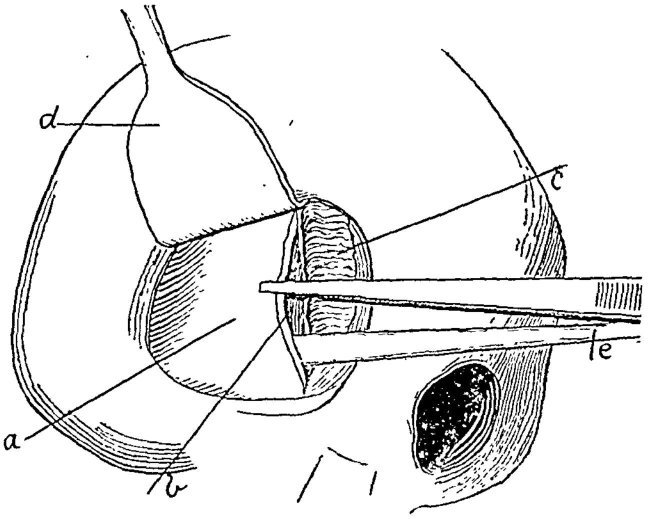

Fig. 11.—Denuded deflection in the right naris seen somewhat from the side. The posterior edge of the slit in the cartilage is held with the rat toothed forceps after it has been lifted up with the elevator; *a*, cartilaginous deflection; *b*, inner surface of the mucosa of the concavity; *c*, anterior flap; *d*, retractor lifting wing of nose; *e*, elevator underneath the cartilage.

In order to overcome the difficulties of the anterior incision, Killian complicates the operation by holding the mucous membrane sac open with the blades of his long speculum for rhinoscopia media. An instrument of this kind takes up too much room in the nasal fossa, blocks the nostril and interferes especially with the free use of forceps for cutting away bone.

Another objection to the mucous membrane incision far in front is the fact that it coincides with the first cut through the cartilage, so that, should the mucosa of the concavity be accidentally pierced in making this cut, a penetrating wound straight through both the coverings of the septum will result, and hence often a permanent perforation of the septum, while my anterior flap in this region overlies an accidental hole through the mucosa of the concavity and closes it. The foremost part of the septum is the worst place for a perforation, as it crusts for a long time and is evident to the patient.

My incisions for the other varieties of deviations mentioned are also all designed to make the deepest part of the deflection accessible.

Instruments for Separation of Mucous Membrane.—Most of the instruments devised for this part of the work are unnecessarily large and massive, and the heavy bone implements of the general surgeon seem to have served as models for them. The problem is not so much to scrape off the perichondrium and periosteum from the septum as one would denude the tibia as to carefully undermine the coverings of the deflection, for the instruments, on account of the position of the septum between two narrow cavities, must of necessity work nearly parallel to the surface attacked so that scraping is only possible to a limited extent in front. In addition, the soft, yielding, springy cartilage is not as suitable as bone for scraping with chisel-edged instruments. The undermining must be done in narrowest places, around corners and often at a great depth in the naris, by actual measurement in many of my cases two to three inches behind the front of the external nostril. The type of elevator demanded is, therefore, thin-bladed and flat, so that it may undermine readily, narrow so that it may fit small nares, long so that it may reach places deep in the nasal fossa, and gently curved so that it may work around corners and always keep its edge close to the surface to be denuded, lest it perforate the mucosa. A sharp and dull separator are needed, the dull one being merely without keen edge, but never blunt, as blunt instruments perforate readily by punching through in front of adherent places. The sharp elevator and, in addition, my round-edged knives of various patterns (Fig. 7, L, E, D) are used for keen dissection in places where the covering of the septum is adherent. In many cases all of the separation may be done with the dulled separator, but the crests of deflection, the bottom of the concavity, cicatrices after previous operative attempts, often both sides of the crista incisiva and vomer below the horizontal angle of deflection and the foremost part of the cartilage, are places where the covering may need to be dissected away with keen blades.

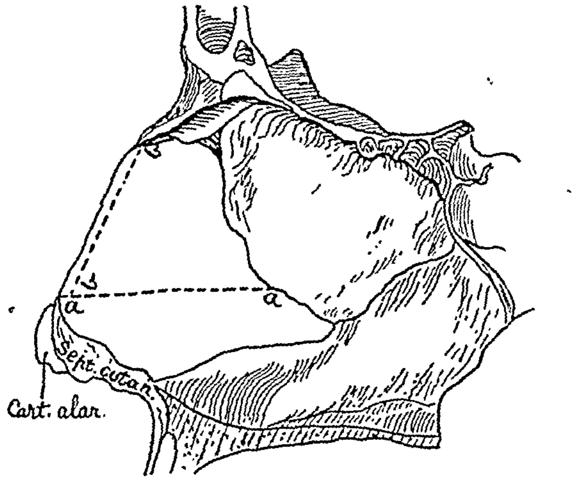

Fig. 12. The nasal septum; *aa*, line below which the cartilage may be completely removed; *bb*, posterior limit of strip of cartilage under nasal bridge to be preserved.

In addition to the long elevators mentioned, it is a great convenience to have a short-bladed pair for uplifting the mucosa in the front of the naris, for the closer to its working point that an instrument is held the easier is it to direct its motion and the finer is its guidance.

A thing to avoid in the construction of instruments for the resection of deflections is the so-called nasal angle. This is an angular attachment of the handle to the shank designed to keep the hand below the level of the nose under the supposition that it gets in the way of sight when holding a straight implement, and a number of instruments for the submucous resection are now made in this manner. Mine are all straight, yet I can always see the field of operation perfectly. Even slight pressure against the distal end of an angular instrument tends to rotate the handle, which, therefore, has to be held firmly either in the fingers or, as is easiest, grasped in the whole hand. This effort implies a stiff wrist and fingers and makes it necessary to make the motions of the instrument with the coarse muscles of the arm and shoulder, instead of the finer ones of the hand and fingers, which are capable of more accurate and controlled work. The presence of an angle also complicates the movements needed and disturbs the sense of direction.

Separation of Mucosa on Convex Side.—The mucous membrane and perichondrium of the septum form two distinct layers. The perichondrium is thin and transparent and is readily overlooked, because the whiteness of the cartilage shines through it. The inexperienced operator, therefore, is apt to attempt to lift the mucosa from the perichondrium, a difficult task even for keen blades, under the impression that he is baring the cartilage, when he is really leaving it still covered with its thin film of perichondrium. Had he passed his dulled separator under the perichondrium, between it and the cartilage, the undermining of the covering of the deflection would have been a simple matter. It is, therefore, necessary to search for the beginning of the thin membrane of perichondrium at the edges of the incisions, gently scraping it up with the dulled separator until the instrument will pass underneath it. Nevertheless, there are often places where the perichondrium or periosteum clings to cartilage or bone, and the sharp dissectors are needed in such regions. In this manner, in double-angled deflections, the anterior flap should be reflected (Fig. 10) a little beyond the limits of the deflection, so that it will fold back and stay out of the way.

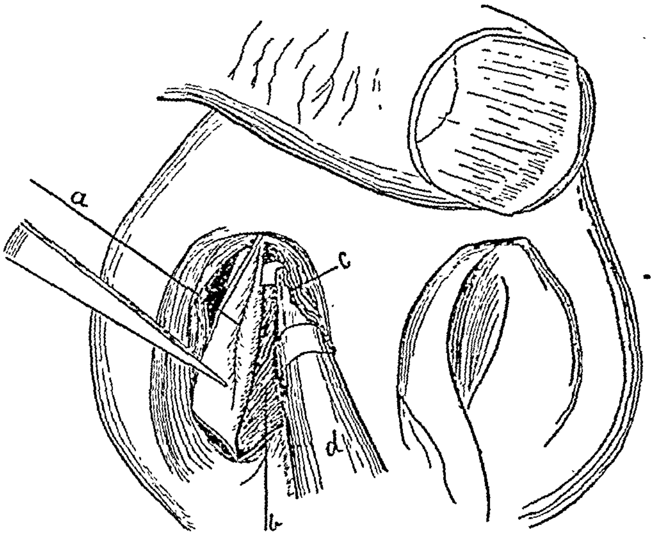

Fig. 13. The cartilaginous deflection, including the vertical angle, *a*, has been cut through at its base and in front and is being severed behind and above by the angular cartilage knives; *b*, inner surface of the mucosa of the concavity of the deflection; *c*, anterior flap folded out of the way; *d*, angular cartilage knife.

The pocket of mucous membrane behind the vertical angle is next made by undermining perichondrium and periosteum over the entire remaining area of deflection backward and, if possible, downward to the base of the septum. Along the crest of and below the horizontal angle of deflection keen dissection with the sharp elevator may be required, and the elevation of the mucosa in this region may be so difficult that it may have to be deferred until the resection of a part of the cartilage makes it more accessible.

In the anterior crestlike deflections an upper flap is made, large enough to fold upward as much out of the way as possible. The separation is then continued below the horizontal crest, a mucous membrane pocket being created which reaches the base of the septum, the crista incisiva and vomer being thus bared below the horizontal angle (Fig. 3). As stated, sharp dissection is often needed in this region.

In deep-seated deflections beginning near the bony septum the separation is conducted from the vertical cut in front of the deviation described (Fig. 8).

In the anterior deflections that require dissection from the free border of the quadrangular cartilage in the naris of the concavity, keen dissection with the round-bladed knife (Fig. 7, E) is sometimes needed for a distance back of about three-fourths of an inch before dull separation becomes possible.

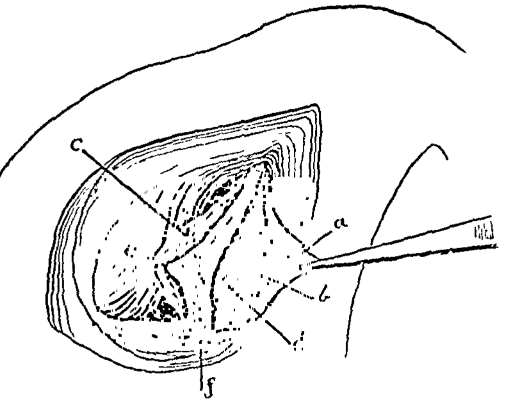

Fig. 14. V-shaped profile of bony deflection seen after removal of cartilaginous deviation: *a*, anterior flap: *b*, anterior cut edge of cartilage: *c*, separated mucosa of convexity of deflection: *d*, inner surface of mucosa of concavity of deflection; *e*, inferior turbinate; *f*, vomer.

First Cut Through the Cartilage.—A clean cut through the cartilage with my thin-bladed, razor-edged knife (Fig. 7, D or E) is less apt to perforate the mucous membrane of the concavity than tedious scratching through with a thicker-edged, sharp instrument, for the thin knife cuts through with slight strokes and is held lightly like a pen in relaxed fingers, while it is necessary to seize the thick-bladed instrument more firmly in order to make the pressure on the septum needed to make it cut, a pressure which is apt to make it suddenly plunge through the mucosa of the concavity when the cartilage is pierced. The light stroke used in cutting with a thin blade permits a delicate sense of touch which tells the operator when he has penetrated the cartilage. I have abandoned the use of the little finger in the other nostril to feel for the edge of the knife under the mucosa, as it presses the mucous membrane against the advancing edge and so favors a perforation. When the knife seems to have severed the cartilage along a line of about one-half an inch, the cut edge is felt for with a dull spatula, lifted up, and seized with delicate rat-toothed forceps (Fig. 11) which pull on it while the penetrating cut is finished with the severed edge of cartilage in plain view as a guide. I always operate with the right hand, no matter in which nostril the deflection lies.

Before making the first cartilaginous incision in the common double-angled deflections the anterior flap is held out of the way with the retractor which holds the nostril open or with a fine double tenaculum. The first cut through the cartilage is then made as formerly, along the entire base of the reflected anterior flap (Fig. 10, *a. b.*) In the region below the level of the anterior angle of the quadrangular cartilage, that is, below the upper boundary of the alæ nasi, the incision may be made at the very front of the cartilage of the septum, if the deflection extend so far in front, above this boundary, where the quadrangular cartilage underlies the lateral cartilage of the external nose (Fig. 12), the incision should leave a distance of at least one-half a centimeter, about a quarter of an inch, between it and the under surface of the nasal bridge in order to insure its support, for Mueller and Menzel claim to have seen slight sinking in of the nasal bridge in this region. I have never myself seen this in any case nor does Killian mention it in his description.

I no longer conduct the whole of the elevation of the mucosa of the concave side through a single anterior incision in the cartilage, but join to my first penetrating cut a short second one (Fig. 10, *b. c.*) along the base of the septum, cutting through the cartilage from without as in the first cut or else separating a little of the mucosa of the concavity and cutting through the cartilage from underneath after introducing one of the knives under it. This produces an angular cartilaginous flap (Fig. 10, *a b c*), which gives more room for freeing the mucosa of the concavity than the older single cut did, in fact the pulling aside of this cartilaginous flap gives so perfect a view of the mucosa of the concavity and of the separator uplifting it that I no longer find it necessary to watch the motions of the instrument underneath the covering of the septum from the naris of the concavity as I formerly did, nor do I even think this advisable, for one is less certain to avoid a perforation under these conditions than when the blade of the elevator is actually seen as it separates mucosa from cartilage.

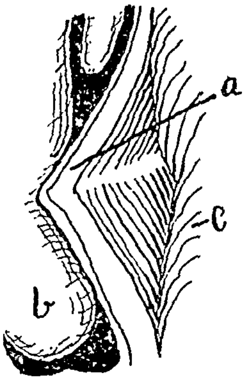

Fig. 15. V-shaped bony deflection seen after resection of the cartilage, pressing firmly into inferior turbinated body; *a*, bony deflection; *b*, inferior turbinate; *c*, mucosa of concavity.

When the vertical angle of deflection is situated very far forward and is unusually acute, its anterior plane extending transversely across the nostril or even curving towards the observer, I have found it best to make the first cut in the cartilage along the crest of the vertical angle of deflection, in the same line as the vertical cut in the mucosa, and to elevate the mucous membrane of the concavity of the deviation by working backward and forward underneath the cartilage from this first cut.

In the crestlike deflections the first incision in the cartilage is made vertically in the plane septum just in front of the beginning of the deflection. (Fig. 3, *c*). This plan is adhered to even when the deflection is wholly of bone, the cartilage being undermined until the bone is reached.

Separation of Mucosa on Concave Side.—The pulling aside of the cartilaginous flap described, gives such a perfect view into the pouch of mucous membrane on the concave side of the deflection, formed by the progressing separation of the mucosa from the cartilage and bone, that this part of the operation can be done much more rapidly than by my former method of working through a slit in the cartilage, and with far less danger of a perforation.

In adherent places the covering may be dissected off with exactness in full view, with the sharp elevator (Fig. 7, L). In most cases the liberation of the mucosa may be done throughout with the dulled elevator, but not infrequently places are encountered where the perichondrium or periosteum are firmly grown onto a cartilage or bone as the result of previous operations or inflammations or where vessels enter osseous substance.

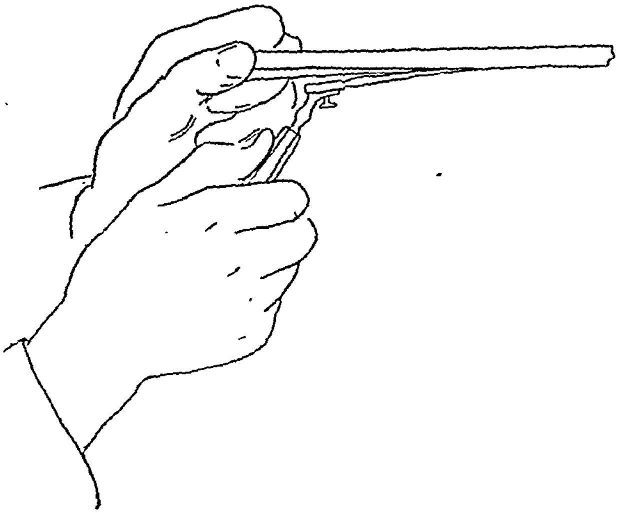

Fig. 16. Strip of bismuth lint pulled taut against end of probe for introduction.

In such places blunt instruments fail to progress and if force be used punch through the mucous covering. In fact the safety from perforation supposed to be offered by thick, blunt instruments is imaginary, for they plunge through more readily than thin ones, as much pressure is needed to undermine with them.

The most difficult separation is usually found in the deepest pit or trough of the concavity and below this on the side of the vomer and crista incisiva and the separation of the periosteum from these regions may have to be deferred until the resection of the cartilage gives freer access.

The separation on the concave side is not complete until the mucous membrane hangs away from the hollow of the deflection and the septum looks straight in the nostril of the concavity.

Resection of the Cartilage.—Before cutting away the cartilage the operator must be sure that it is entirely bared of its coverings on both sides lest a piece of mucosa be torn out with it when it is removed.

I have seen no reason for changing my original method of cutting out the cartilaginous deflection. I regard this as the easiest part of the operation and commonly succeed in removing all but remnants of the deviation in the cartilage in one piece. I have not felt the need of adopting the forked knives of Killian and Ballenger which can not be used on cartilage which is thick throughout or in places, and which do not apply themselves well to abrupt bends.

The bared cartilage is pulled outward with the rat-toothed forceps, while Ingals' cartilage knife (Fig. 7, H) is introduced underneath it to the back of the pouch of mucosa on the concave side of the deflection. Its point is directed toward the convex side and its back toward the mucosa of the concavity; it is then made to prick through at the bottom and hindmost part of the cartilaginous deflection, and its blade is drawn forward, cutting from underneath outward through the bottom of the cartilaginous deviation along its whole length, thus severing it below. To cut through it at the back, an angular cartilage knife is chosen whose edge looks downward when its point is directed away from the concavity. This knife is also passed to the bottom of the mucous membrane pocket of the concavity underneath the cartilage (Fig. 13), its point turned away from the mucous membrane of the concavity, made to prick through the cartilage at the highest point in the rear of the cartilaginous deflection, and the blade is then made to sweep downward, severing the cartilage at the back. The other of the pair of angular cartilage knives is now inserted into the slit made by the first one, the handle depressed and the blade made to sweep forward, cutting through the cartilage above. The piece is now severed at all of its boundaries and is readily drawn out of the nostril.

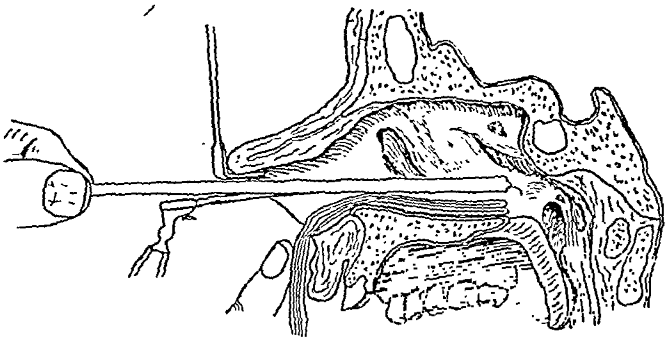

Fig. 17. Lateral view of nasal fossa. Two folded strips of the tampon lie in the naris, the loose ends being held with the finger against the upper lip. A third strip is being introduced stretched against the end of the probe.

If the cartilage be thick, repeated strokes of the knives instead of one cut will finally sever it. For very thick cartilage I have a pair with longer angular blades as a convenience rather than a necessity.

The whole maneuver is done with the aid of vision and under the intelligent guidance of the hand, so that one can exactly outline with the knives the piece to be removed. Remaining vestiges of the cartilaginous deflection may be pared off strip by strip with the angular knives, the sharp separator, or Ingals' knife, and I rarely now use cutting forceps on the cartilage.

Resection of Bony Deflections.—The punch forceps, according to my experience, removes bony deflections with more accuracy and less pain than any other instrument. It should be slender, so as not to obstruct the view and to move freely in the naris; the part in front of the lock should be straight and at least 3½ inches (9 centimeters) long, for bone may have to be cut at a distance of 2½ to 3 inches from the front of the nostril and a little length to spare is needed. The jaws should hinge on a rivet at the end of the forceps, so that they will separate widely in a small space and so that the opening of the instrument will not obstruct the view, as it does when the jaws are moved on the rivet of the lock of the forceps. The forceps should be of the punch variety, one jaw fitting within the other, instead of merely having its cutting edge applied to that of its fellow, as the latter type of instrument will not cut bone unless it be made so heavy that it blocks the nostril. In spite of the qualities of length and slenderness the instrument should be so strong that it will easily cut through the thickest and hardest bone found in the septum.

The Gruenwald forceps, which I have used for years, possesses these qualities to perfection except the last, for bone was occasionally met with which this forceps, strong as it is, could not cut through, or only after its jaws were repeatedly closed on it. I have therefore strengthened Gruenwald's forceps by giving it a forceps handle instead of a scissors handle and by other changes, so that I now have an instrument that will cut through the heaviest bone in the septum, even the crista and anterior end of the vomer, with a moderate pressure of the hand. The slenderness and length of the forceps have been preserved and the jaws open laterally instead of vertically, as in the original, adapting the instrument still better for the septum. The blades are made only partly fenestrated, a ledge remaining designed to preserve the strength of the blade and to retain the exsected pieces and keep them from falling out in the nose. My modified forceps,[1] like Gruenwald's, is made in three sizes. (Fig. 7, T). The operator needs the middle and smallest sizes. The large one is an occasional convenience.

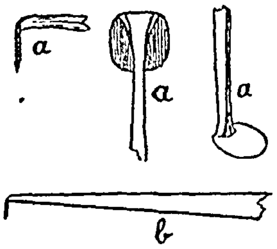

Fig. 18.—Hoe-shaped spatula for insertion into first cut in cartilage in order to pull the severed posterior edge outward so that the elevator may be passed underneath the cartilage. Useful where the deflection extends to the front of the nostril. Not mentioned in the text. *a, a, a,* enlarged views; *b,* natural size.

The forceps is made in sets of two of right and left pattern, for it is convenient to use the fixed jaw, which has a smoothly rounded end, to push away the undermined mucosa should it apply itself to the bone on one or the other side of the deflection. On one side it always hangs away, commonly on the side of the concavity.

In addition to the punch forceps a chisel and mallet is sometimes needed to cut away the crista incisiva and anterior end of the vomer from the nasal floor.

Removal of the Bone.—The bony part of the operation receives such slight mention from most authors, and the means described for its performance are so inadequate, that the inference is natural that it is frequently not thoroughly done. Yet it is often the most difficult act of the resection, and unless all vestiges of the bony deviation be removed a half result is likely to occur, for which the surgeon will always feel apologetic.

In most bony deflections, in looking directly backward in the naris of the convexity, after completion of the resection of the cartilage, the steep superior border of the vomer is seen joined above, at an angle caused by the deflection, by the anterior inferior border of the perpendicular plate or more often by a remnant of cartilage which is the posterior angle of the quadrangular cartilage of the septum. The angle of deflection mentioned is the horizontal angle in vertical section, and it appears like a V lying on its side (Fig. 14), and it is this V which is to be followed up with the punch forceps until all of it is cut away and disappears and a plane part of the bony septum is reached behind it.

Looking downward at the floor of the nose the continuation forward of the superior border of the vomer and of the crista incisiva are seen, freed of cartilage, the vomer and crista curving over towards the naris of the convexity, sometimes so strongly that they lie nearly flat on the nasal floor, making the surface belonging to the concave side look upward and simulate the bottom of the naris.

The bony resection begins with the extirpation of the posterior V mentioned. On the concave side the mucosa usually hangs away from the V, leaving a space for the forceps blade, but the mucous membrane on the convex side is often kept closely applied because the bony V is wedged firmly against the inferior turbinated body. (Fig. 15). In such cases I have often had to spring it off with the spatula in order to insert the blade of the forceps. The spatula here also protects the mucosa by holding it against the turbinate. Nevertheless, in exsecting such deepseated, extreme bony deflections it is not always possible to preserve the hindmost, invisible part of the mucosa of the convexity and it is better to sacrifice it rather than to leave a part of the deviation behind in the depths of the naris. In some cases it is necessary to resect the bone to near the posterior border of the vomer. The forceps described cleanly cuts away the bone, piece by piece, and with surprising ease.

After the resection of the V posteriorly the curved over maxillary crest and front of the vomer, on the nasal floor, next need removal. They should be reinspected to see whether they are denuded of their covering, for though it may often be readily enough lifted off, its separation over these bony parts is often so difficult that it has to be put off until the last. It is frequently firmly adherent because, as is well described by Killian, the front end of the vomer and the crista in many instances are enveloped in their own periosteum, which, therefore, covers their upper border after the cartilage has been resected from it. This periosteum is continuous with and has the same color as the perichondrium lining the inner surface of the mucosa of the concavity, so that no boundary is visible where the latter is reflected onto the bone, and the edge of the bone can therefore not be seen, but must be felt for and cut down on with the round-edged knife. In most instances the bone then has to be dissected out from its coverings by keen dissection with the sharp elevator.

When the anterior end of the vomer and the crista stand bare, they may be cut away with my forceps if they project enough to be seized with it. If not, they may be chiseled away close to the nasal floor, the resulting fragment being removed with dressing forceps. The chisel is only suited to the strong, well supported base of the bony septum and should not be used higher up on it as it is apt to break the frail bone here and create far-reaching fissures. Breaking out of pieces by twisting with forceps is also to be avoided as it causes great pain and the result of such violence may be fracture into distant regions.

---

[1] Fraenkel's Archiv. f. Laryngologie, vol. xvii, p. 172.

When the resection is complete the flaps will apply themselves smoothly, the septum will look straight and the surgeon can usually see the motions of the levator *palati muscle* in the naso-pharynx through the nostril that contained the convexity of the deflection, in fact I regard the sight of these motions as a proof that the operation is complete and the naris properly freed. No vestige of the deflection should be left behind. If somewhere the mucous membrane of the convexity will not lie flat against the septum one may be certain that there is still a projecting remnant of cartilage or bone to resect underneath it. The concave side should also be inspected to see whether the hollow be effected.

The Tamponade.—I still use sterilized lint, impregnated with powdered subnitrate of bismuth, for my tampon, and in no case, even when the plug has been left in the nose for a week, has it become offensive. The lint is cut in ribbons ¼ of an inch wide and 10 inches long. To begin packing a strip is folded in the middle, the end being held between the thumb and index finger of the left hand, while the right pushes the end of a stiff nasal probe such as Gruenwald's, against the bottom of the fold to hold the strip taut. (Fig. 16). Its ends may also be held with the thumb and finger of the same hand that holds the probe. The strip, stretched in this manner, is passed in along the nasal floor to a little beyond the posterior end of the window, care being taken to follow along the outer wall of the naris so as not to derange the flaps. The strip is then pressed down on the nasal floor with the probe. If the resection of a crestlike deflection has left an inferior pocket of mucosa, it is to be supported by the strip. In the same manner successive strips are then introduced (Fig. 17), one above the other, until the nose is nearly full, the ends of those in the naris being held against the upper lip with a finger while the next one is passed in. As the tampon builds up it sustains the flaps so that they cannot become displaced. They are not always redundant enough to meet exactly at their edges, but a small, raw surface left by their retraction is of no moment. The last strip is longer than the others and is tucked in on top of them in successive little folds until the naris is completely filled.

This packing may be relied on to prevent hemorrhage. A free watery discharge usually sets in an hour or two after the operation and as it is tinged with blood it is apt to make the patient think that he is bleeding and to lead him needlessly to disturb the surgeon unless he be told beforehand to expect an outflow from his nose.

The removal of the packing is begun on the second day after the operation, when the top strip is removed and as much of the rest as will pull out easily. When all hold fast or if there be a little bleeding the removal of the remainder of the packing is deferred until the third or fourth day. The parallel situation of the strips prevents excessive bulging of the mucosa over the window into the naris of the concavity.

The patient only needs to stay in bed on the first day after the operation. After that he may be up and about, but should not work for a week.

For the first week after the removal of the tampon the naris is kept closed with a pledget of cotton placed in the nasal vestibule by the patient and frequently renewed. This excludes dust and keeps the mucosa moist. After this period the patient may use the nostril for breathing, is told to spray it out with normal salt solution and to insert a little plug of wet cotton in the nostril for a few hours, whenever it is necessary to soften secretion. In addition an ointment of salicylic acid, 10 grains, to 6 drams of lanolin and 2 drams of vaselin is swabbed into the nasal vestibule by the patient to prevent hardened mucus from adhering. After four to six weeks the nose needs no further treatment.

This concludes my description. To many it may seem needlessly elaborate and detailed, especially as a number of authors have spoken of the submucous resection as an easy little operation that any one may perform with a few simple instruments. I regard these statements as misleading and likely to bring discredit on the method and my experience shows me that those who make them must be either men of little experience or not thorough in extirpating deflections, especially their more difficult bony portions.

In a number of resections there are many that are performed with surprising ease, and a series of these is apt to lead the surgeon to think that all of them may be done with like facility until a succession of operations, requiring great skill and patience, show him what difficulties may be encountered, especially in completely resecting bony deflections.

I do not claim that my method is the only way, but I assure those who will follow my directions exactly that they will not fail to remove, radically, any deflection, no matter what its form, nor how deepseated it may be, and it is for their guidance that I have so minutely described a method which, since it has become complete, has invariably given me a successful result and permanent relief to the patient with a minimum of traumatism.

Of late stress has been laid by some authors on completing the operation rapidly, as if there were need for haste. As in other procedures requiring care, delicate manipulation of frail structures and deliberation, any attempt to rush the work is apt to end disastrously by producing perforations, excessive traumatism and often an incomplete result. Haste makes a forcible, rough operation of one the very nature of which is neatness, deftness and painstaking. The temptation is great to proceed in spite of hemorrhage, and to work blindly in a field obscured by oozing of blood, or to elevate the mucous membrane, or cut away bone without the use of sight. Vision of the field of operation is essential to thorough work and the avoidance of perforations.

I see no need whatever for haste. The patient is not suffering pain. Even little children have endured the operation without complaint when the local anesthesia was made as I have described. The time lost by the surgeon in deliberate work should be gladly sacrificed in the interest of a more thorough operation for his patient. The chief source of delay is the oozing of blood in spite of adrenalin, especially from the bony parts of the field. If this occurs the operator should stop his work until renewed applications of adrenalin or cocain have arrested the hemorrhage, or until it has stopped of its own accord. Always work in a bloodless field if possible, even though to do so lengthens the operation.

DISCUSSION.

Dr. W. S. Anderson, Detroit, uses the head mirror instead of the lamp. If the mirror is used over one eye the rays are parallel. It has seemed to him an advantage to use both hands in this operation, and when operating on the right nostril he makes the incision with the left hand. Dr. Freer's modification of the Gruenwald forcep is a good modification, for probably all have had some difficulty working with the ordinary Gruenwald forcep. Experimental work has shown that, at least in some cases cartilage, or very dense connective tissue, is again deposited between the layers of mucous membrane. It is surprising how firm the septum becomes in those patients who have been operated on a few months previously. In Dr. Anderson's series of operations he had a larger portion of perforations in his early cases than he ought to have had. He now has very few, and he believes that as one develops in this work the perforations will become rare; it seems to be impossible entirely to eliminate them. Fortunately the functional results are good even if there is a small perforation. Frequently rhinologists say that small perforations should not be regarded, but Dr. Anderson feels that a perforation means poor surgery.

Dr. Cullen F. Welty, San Francisco, said that Dr. Mensel's modification of the Krieg-Bönninghaus operation accomplishes the same as the operation demonstrated by Dr. Freer. He described the operation in detail, because he thinks it has many points of advantage, and is not so difficult of execution: A single incision is made in front just over the point of the cartilaginous septum, carried well to the floor of the nose. It must be remembered that the perichondrium is very adherent at this place, and particular skill must be exercised to avoid a perforation. In using the sharp or the blunt elevator the point should be kept turned well to the septum. Through this incision the whole of the deflected part of the septum is removed. After removing some of the cartilage the nasal speculum can be introduced into the cavity, and every step of the operation can be followed by the eye. After the perichondrium and mucous membrane have been sufficiently elevated on either side to overcome the obstruction the cartilage is cut above and below with small scissors; after this a sharp double curette is used to remove as much of the cartilage and bone as is necessary. This may also be removed by a strong forceps, with a twisting motion. In some instances a spur will be encountered. The perichondrium and mucous membrane are more adherent at such places, and particular care must be used not to cause perforation. The chances are very small of making a perforation on both sides at the same point. If the perforations are at different places the septum will be perfectly good. In case there is a thick, bony spur, which can not be removed with a double curette, a small chisel is very useful. In case an operation of any kind has been done previously on the septum the perichondrium is unusually adherent, and a perforation is most likely unless great care is observed. Twenty per cent. solution cocain is rubbed well into the mucous membrane on both sides of the septum until the patient can not feel the friction; 0.1 per cent. Schleich's solution is injected into the line of incision and on both sides of the mucous membrane until it becomes white. Adrenalin aids in keeping the operative field free from blood. The instruments necessary for this operation are nasal speculum, blunt and sharp elevator, double curette, small scissors, small chisel, anatomic forceps, two blunt retractors and, in some instances, a needle and thread. This operation originated by an accident, and Dr. Welty was the one to suggest its present form. He made a perforation by the old method, and maintained that had he not cut away the mucous membrane of the other side this perforation would have closed when brought in apposition. This happened some two years ago, when he had an *Arbeitsplatz* in Hajek's clinic. He stated that the only point to which exception can be taken is that in this operation the incision begins at the tip of the cartilage, while in the other operations it begins at the point of deflection. It remains to be demonstrated that harm can be done by removal of this anterior part.

Dr. Hill Hastings, Los Angeles, said that in the operations on the bony septum he has not been so successful. Particularly under ether he has had a good deal of trouble, so that he has almost doubted the wisdom of operating under a general anesthetic. He operated in two cases that were failures under the Ashe operation, and in one case got a good result and in the other case a fair result. He asked the position of the patient recommended by Dr. Freer, and any difficulties he encountered under general anesthesia, and whether he has had any mortality or any trouble that might be attributed to the anesthesia.

Dr. George L. Richards, Fall River, Mass., said that if the operator has two assistants he can put the patient down and lift up the nose as Dr. Freer describes, but many have to operate with one assistant. Dr. Richards usually operates with the patient in the upright position. He has not had difficulty with the patient fainting. He tells them at the beginning that they will probably feel faint and sweat a few minutes. After this the anesthesia seems more profound and the patient will not give trouble by fainting. He always has the nurse stand immediately behind the patient. When it comes to using the chisel, he has taught his nurse to give a graduated blow just as the dentists teach their assistants. There will be very few perforations by any method if the operator can get all the cartilage off without injuring the opposite side. If one sets out to do the operation Dr. Welty has just described, which is practically the same as that of Killian, and one does get a perforation on one side, it does not matter, for then it is simply converted into another form of operation. Perforation in the old operations occurred so frequently because the operator did not get the two mucoperichondrium surfaces together. If these are separated by a bit of cartilage they will not unite. Dr. Richards thinks Dr. Freer did Dr. Killian a little injustice. He did not mention that the Killian knife has a double cutting surface. Dr. Ballenger's knife is arranged so that it may be used with facility. It is useless to say how many minutes is required to do the operation. What is desired is a good result from the operation rather than any saving of time. The operation that can be done in the simplest way and in the shortest time by most operators is through an incision somewhere in front. The muco-perichondrium is more adherent in front. To Dr. Richards the most satisfactory operation is with an incision in front, where the edge of the cartilage presents, such as Heik recommends, or a little farther back. Then with anything in the way of an elevator the perichondrium can be slipped back and the separation made. He does not attempt to remove any of the cartilage until the separation is complete. Then the cartilage and bone can be easily removed. It seems to him impossible that the forceps will do all that Dr. Freer states; he prefers a chisel on the nasal floor.

Dr. George F. Cott, Buffalo, N. Y., declared each succeeding year makes the operation more difficult to understand. Dr. Welty has cut down the operation about 75 per cent., and Dr. Cott would like to cut down about one-half of the after-treatment. There is no difficulty from bleeding after the first twenty-four or forty-eight hours, and the patients may be permitted to breathe through the nose on the third day. In regard to perforations, in the ten cases in which Dr. Cott has operated during the past year, none of the patients have had perforations. It makes no difference whether part of the mucous membrane is destroyed on one side so long as the other side is intact. The instrument Dr. Freer has described, to go back through the posterior part of the nose and cut forward, may be useful in Dr. Freer's hands, but probably will not be popular with the profession in general.

Dr. L. C. Cline, Indianapolis, said that the lesson to be drawn from the great number of instruments recommended is not to make more instruments, but to see if we can not get along with less. He uses comparatively few instruments. Dr. Cline does not believe in making very extensive cuts in the mucous membrane. After making a small cut the membrane can be stretched and forceps and chisel can be used to remove the septum. Very little packing in the nose will cause pressure. The cartilage and bone should be cleared out so that it requires only sufficient packing to hold the membrane in place. It is better to leave the nostril open as much as possible so as to have the stimulation of the air.

Dr. Gardner Perry Pond, San Francisco, declared that Dr. Freer's position as to the trouble and inconvenience from frequent attacks of syncope on the part of the patient is well taken. It is extremely annoying. He does not understand the objection to general anesthesia in these cases. If a posterior plug is put in while doing the work in the anterior part of the nose it will do away with the draining back of the blood into the throat. Dr. Welty's operation is beautiful for a simple cartilaginous bend, but when there is a posterior bony ridge, or one low on the floor of the nose, the procedure he suggests will not enable the operator to get at it readily. The trephine on the dental engine works well in these latter cases. With it one can take out the greater portion of the bone and the rest may be trimmed out with forceps.

DR. GEORGE A. LELAND, Boston, agreed that there is an advantage in using few instruments. He was much impressed with Jansen's operation last summer because of its simplicity. This operator uses only a nasal speculum, a small scalpel, dressing forceps, a rather sharp elevator, and a cutting forceps, finishing with a needle holder and needle to suture the edges of the wound. If there is a bony exostosis he may also need a chisel, the mallet being used by an attendant. With these few instruments the operation is performed with marvelous neatness and dispatch. The great question in these operations is as to whether some time in the future there may not be a depression of the bridge. This operation has not been in vogue long enough to be sure that this result may not follow. A recent writer* says that if the cartilage is removed too high up the bridge of the nose may sink in. Hence comes the question how high up is one justified in removing the firm part of the septum. It has been said that this is not a support, but only a partition. To sustain this view a few cases of the loss of the whole of the septum without depression in specific disease are cited. Here, however, the question of time must come in. We frequently see a recent loss of septum where there is no depression, but after a number of years the relative positions may be much different. Dr. Leland said that this brings to mind a case seen some fifteen years ago. A physician from the far East desired to have a very much sunken bridge of his nose restored to its former position. He was about 50 years of age. When he was a student at the Bowdoin Medical College, Dr. Green, Maine's most eminent surgeon, in order to give him breathing space, with a scalpel removed the projecting part of a deflected septum from the left nostril. This made a very large perforation through the septum and yet there was a considerable amount of cartilage in the apex between the wings. The bridge remained up for a number of years, but after 20 or 25 years it had sunk in so as to produce a marked deformity. This would seem to show that the septum is a support as well as a partition. It is said by some that the cartilage is reproduced between the two layers of the perichondrium after they are brought back to the position we wish to obtain. It is said also by others that there is no production of true cartilage, but that between the layers of the perichondrium round celled infiltration takes place, which, according to its law produces a fibrous layer. In such cases, therefore, there may be not only the action of gravitation, but also that of contraction of this fibrous tissue, a double reason for sagging of the bridge. Of course this is only one case, but rhinologists have not yet been doing this operation more than about nine years, at least Jansen has been doing it nine years; hence Dr. Leland thinks that they are not in a position now to tell whether these bridges are going to sink in or not, and he cautioned taking away as little of the cartilage as possible, as he is by no means sure that some bold operators may not be producing noses which will be greatly deformed after they who have produced them have passed on beyond the reach of adverse criticism and lawsuits.

A. A. GREENE, Anniston, Ala., said that Dr. Leland's remarks reminded him of a case he saw in which a large perforation had existed for over 35 years. The patient was a physician who had had the perforation when a student. The perforation is almost as large as a half dollar and there is no depression of the nose whatever. If the bony support is removed to a great extent there probably will be depressions, but sagging will not necessarily result from removal of the cartilage.

DR. A. DEVILBISS, Toledo, Ohio, said that he believes that there is much less danger of the ultimate production of a saddle-back nose if the membrane is all dissected back and membrane, bone, cartilage and all removed than when the membrane is left. For the last twenty years it has been his custom when there is a little hole in the septum to cut out enough bone and cartilage to have mucous membrane enough to cover the edge of the hole; this prevents crust formation. He would do the same were he to make an opening in the septum to secure free inspection. The long-continued pulling on the bridge is an important factor; there may be a depression from the constant drawing. Fibrous tissue will fill in the part where bone is removed and cartilage will grow in again when cartilage has been removed. Dr. DeVilbiss does not advise making promiscuous openings in these cases; the cases should be carefully selected.

DR. JOHN F. BARNHILL, Indianapolis, said that on several occasions this subject has come up in the Section meetings of the American Medical Association, and it has always brought out a great deal of discussion, certainly sufficient to give us to understand that this is not an operation for everyone to do and to expect to get satisfactory results in each case. These operations are difficult to perform. Each patient should be studied carefully and a suitable method devised for the particular case before the operation is begun. If rhinologists were to follow any one method in all the cases, disaster would result in a great many. After having done the operation as Dr. Freer directs it looks less formidable to Dr. Barnhill than before. Dr. Barnhill does not so often find the typical ridges Dr. Freer mentions, and often the mucous membrane is densely adherent, so that he has not been able to remove the cartilage without great danger of perforation. Some of Dr. Freer's instruments, especially those he uses for lifting the alæ of the nose, Dr. Barnhill has been unable to use. His assistant seems never able to hold the nostrils in as good position as can be secured by the use of the Myles speculum. He called attention to that class of angular deflection in which the crest lies so low in the nostril as to be apparently imbedded in the tissues of this region. If only the deflected portion above this low lying ridge is removed in the dissection, and the imbedded portion not included, that portion of the cartilage still remaining on the floor would hold the membranous flaps in a position far to one side, and practically so nearly in the old position as to give entirely unsatisfactory results. Dr. Barnhill has operated in several such cases, one of which failed because the exact condition was not previously recognized. The typical case as described by Dr. Freer has been somewhat uncommon in Dr. Barnhill's practice, and, therefore, he has been unable to follow the exact technic in a majority of cases. It has been said that small primary incisions are sufficient, but he has not found that true. He always feels better satisfied if he has a large opening through which he can see well, and use his instruments freely. The cartilage can be taken out rather easily, provided it is not greatly thickened or too angular at any point, with the Ballinger knife. When operating near the posterior end of the septum, the operator must do clean work, and this can not be accomplished by twisting and gouging, but only by the use of an instrument that will clearly cut off the parts without injury to the surrounding tissue. The burr has been mentioned as useful in the removal of the posterior bony part in these cases, but Dr. Barnhill does not believe the use of the burr permissible because it is apt to leave splintered parts in the deep membranous pocket which the operator may not be certain to remove. He does not believe any surgeon who is going to close up his wound would think of using the burr. The cutting forceps is much better. The fragments liable to be left by the burr would be irritant and would probably break through later, as would any other foreign body. He does not believe that there is any danger of saddle-back noses, provided nothing is done that will set up such violent inflammation as to cause the adhesions spoken of by Dr. DeVilbiss. The cases of saddle-back noses caused by syphilis are due, not to the fact that the septum is gone, but to the gummatous infiltration with subsequent adhesions which have pulled the tissue down. In submucous resection work, we do not think of causing any such reaction or subsequent contractile tissue.

DR. ROBERT C. MYLES, New York, said that in 1896 he read a paper (THE JOURNAL A. M. A., Sept. 28, 1896), in which he said that he had been operating for several years for the relief of this class of cases with very satisfactory results. He stated that there are two conditions which confront the operator in these cases: a projecting anterior extremity of the triangular cartilage which extends across the vestibular space and approaches the margin of the ala; and the various forms of deflections with more or less thickening of the convex side of the cartilage. In the first class of cases, the space between the ala and the projection is so narrow that when inspiration takes place in a rapid manner the atmospheric pressure forces those patients who have been operated on a few months previously. In Dr. Anderson's series of operations he had a larger portion of perforations in his early cases than he ought to have had. He now has very few, and he believes that as one develops in this work the perforations will become rare; it seems to be impossible entirely to eliminate them. Fortunately the functional results are good even if there is a small perforation. Frequently rhinologists say that small perforations should not be regarded, but Dr. Anderson feels that a perforation means poor surgery.

The trephine on the dental engine works well in these latter cases. With it one can take out the greater portion of the bone and the rest may be trimmed out with forceps.

Dr. George A. Leland, Boston, agreed that there is an advantage in using few instruments. He was much impressed with Jansen's operation last summer because of its simplicity. This operator uses only a nasal speculum, a small scalpel, dressing forceps, a rather sharp elevator, and a cutting forceps, finishing with a needle holder and needle to suture the edges of the wound. If there is a bony exostosis he may also need a chisel, the mallet being used by an attendant. With these few instruments the operation is performed with marvelous neatness and dispatch. The great question in these operations is as to whether some time in the future there may not be a depression of the bridge. This operation has not been in vogue long enough to be sure that this result may not follow. A recent writer* says that if the cartilage is removed too high up the bridge of the nose may sink in. Hence comes the question how high up is one justified in removing the firm part of the septum. It has been said that this is not a support, but only a partition. To sustain this view a few cases of the loss of the whole of the septum without depression in specific disease are cited. Here, however, the question of time must come in. We frequently see a recent loss of septum where there is no depression, but after a number of years the relative positions may be much different. Dr. Leland said that this brings to mind a case seen some fifteen years ago. A physician from the far East desired to have a very much sunken bridge of his nose restored to its former position. He was about 50 years of age. When he was a student at the Bowdoin Medical College, Dr. Green, Maine's most eminent surgeon, in order to give him breathing space, with a scalpel removed the projecting part of a deflected septum from the left nostril. This made a very large perforation through the septum and yet there was a considerable amount of cartilage in the apex between the wings. The bridge remained up for a number of years, but after 20 or 25 years it had sunk in so as to produce a marked deformity. This would seem to show that the septum is a support as well as a partition. It is said by some that the cartilage is reproduced between the two layers of the perichondrium after they are brought back to the position we wish to obtain. It is said also by others that there is no production of true cartilage, but that between the layers of the perichondrium round celled infiltration takes place, which, according to its law produces a fibrous layer. In such cases, therefore, there may be not only the action of gravitation, but also that of contraction of this fibrous tissue, a double reason for sagging of the bridge. Of course this is only one case, but rhinologists have not yet been doing this operation more than about nine years, at least Jansen has been doing it nine years; hence Dr. Leland thinks that they are not in a position now to tell whether these bridges are going to sink in or not, and he cautioned taking away as little of the cartilage as possible, as he is by no means sure that some bold operators may not be producing noses which will be greatly deformed after they who have produced them have passed on beyond the reach of adverse criticism and lawsuits.

A. A. Greene, Anniston, Ala., said that Dr. Leland's remarks reminded him of a case he saw in which a large perforation had existed for over 35 years. The patient was a physician who had had the perforation when a student. The perforation is almost as large as a half dollar and there is no depression of the nose whatever. If the bony support is removed to a great extent there probably will be depressions, but sagging will not necessarily result from removal of the cartilage.

Dr. A. DeVilbiss, Toledo, Ohio, said that he believes that there is much less danger of the ultimate production of a saddle-back nose if the membrane is all dissected back and membrane, bone, cartilage and all removed than when the membrane is left. For the last twenty years it has been his custom when there is a little hole in the septum to cut out enough bone and cartilage to have mucous membrane enough to cover the edge of the hole; this prevents crust formation. He would do the same were he to make an opening in the septum to secure free inspection. The long-continued pulling on the bridge is an important factor; there may be a depression from the constant drawing. Fibrous tissue will fill in the part where bone is removed and cartilage will grow in again when cartilage has been removed. Dr. DeVilbiss does not advise making promiscuous openings in these cases; the cases should be carefully selected.

Dr. John F. Barnhill, Indianapolis, said that on several occasions this subject has come up in the Section meetings of the American Medical Association, and it has always brought out a great deal of discussion, certainly sufficient to give us to understand that this is not an operation for everyone to do and to expect to get satisfactory results in each case. These operations are difficult to perform. Each patient should be studied carefully and a suitable method devised for the particular case before the operation is begun. If rhinologists were to follow any one method in all the cases, disaster would result in a great many. After having done the operation as Dr. Freer directs it looks less formidable to Dr. Barnhill than before. Dr. Barnhill does not so often find the typical ridges Dr. Freer mentions, and often the mucous membrane is densely adherent, so that he has not been able to remove the cartilage without great danger of perforation. Some of Dr. Freer's instruments, especially those he uses for lifting the alæ of the nose, Dr. Barnhill has been unable to use. His assistant seems never able to hold the nostrils in as good position as can be secured by the use of the Myles speculum. He called attention to that class of angular deflection in which the crest lies so low in the nostril as to be apparently imbedded in the tissues of this region. If only the deflected portion above this low lying ridge is removed in the dissection, and the imbedded portion not included, that portion of the cartilage still remaining on the floor would hold the membranous flaps in a position far to one side, and practically so nearly in the old position as to give entirely unsatisfactory results. Dr. Barnhill has operated in several such cases, one of which failed because the exact condition was not previously recognized. The typical case as described by Dr. Freer has been somewhat uncommon in Dr. Barnhill's practice, and, therefore, he has been unable to follow the exact technic in a majority of cases. It has been said that small primary incisions are sufficient, but he has not found that true. He always feels better satisfied if he has a large opening through which he can see well, and use his instruments freely. The cartilage can be taken out rather easily, provided it is not greatly thickened or too angular at any point, with the Ballinger knife. When operating near the posterior end of the septum, the operator must do clean work, and this can not be accomplished by twisting and gouging, but only by the use of an instrument that will clearly cut off the parts without injury to the surrounding tissue. The burr has been mentioned as useful in the removal of the posterior bony part in these cases, but Dr. Barnhill does not believe the use of the burr permissible because it is apt to leave splintered parts in the deep membranous pocket which the operator may not be certain to remove. He does not believe any surgeon who is going to close up his wound would think of using the burr. The cutting forceps is much better. The fragments liable to be left by the burr would be irritant and would probably break through later, as would any other foreign body. He does not believe that there is any danger of saddle-back noses, provided nothing is done that will set up such violent inflammation as to cause the adhesions spoken of by Dr. DeVilbiss. The cases of saddle-back noses caused by syphilis are due, not to the fact that the septum is gone, but to the gummatous infiltration with subsequent adhesions which have pulled the tissue down. In submucous resection work, we do not think of causing any such reaction or subsequent contractile tissue.

Dr. Robert C. Myles, New York, said that in 1896 he read a paper (The Journal A. M. A., Sept. 28, 1896), in which he said that he had been operating for several years for the relief of this class of cases with very satisfactory results. He stated that there are two conditions which confront the operator in these cases: a projecting anterior extremity of the triangular cartilage which extends across the vestibular space and approaches the margin of the ala; and the various forms of deflections with more or less thickening of the convex side of the cartilage. In the first class of cases, the space between the ala and the projection is so narrow that when inspiration takes place in a rapid manner the atmospheric pressure f

The gastric juice of the dog, in one instance, failed to kill it after six hours' exposure, although it had the power of prohibiting proliferation.

Virulence.

The bacillus of human tuberculosis, although fairly constant in its virulence, may be attenuated by various means. Its prolonged existence in putrid sputum decreases its virulence and a similar decrease occurs on potato, in old cultures or in those which contain iodoform, boracic acid and some other substances. Inoculation with such cultures produces a chronic form of tuberculosis in animals which may heal. In other instances cultures which have grown on artificial media for many years retained their original virulence.

The organism contains about 90 per cent. of water. One-fourth of a dried bacterial mass may be extracted as a wax-like or fat-like substance by a mixture of alcohol and ether. The acid-fast staining property of the bacillus depends on this substance. The remaining portion of the mass, consisting largely of proteins, which may be extracted by dilute alkalies, contains a toxic nucleo-albumin. Cellulose, representing a portion of the capsular substance, is also found in the residue.

Toxic Products.

Killed cultures when given subcutaneously produce necrosis, abscesses, caseation, marasmus, and a subnormal temperature. When given to rabbits and guinea-pigs intravenously they cause rapid emaciation and death in from a few days to a few weeks. By beginning with very minute doses, however, the animals may be gradually habituated to intoxication by the dead bacilli and eventually withstand large doses. The same holds true of the various toxic substances, including tuberculin, which may be extracted from cultures. The proteins and alkaline extracts abscesses when given subcutaneously. which contained all the bacterial constituents and which at the same time is readily absorbed without abscess formation. For its preparation dried masses of the organism are ground up in an agate mortar and after suspension in distilled water and centrifugation, the emulsion consists of two layers. The overlying opalescent whitish fluid was designated as "TO" (Tuberculin Obers). After removal of the fluid from the precipitate the latter was again dried and ground, suspended in water and centrifugated as before, and the process repeated until none of the sediment remained. The different fractions of fluid, except the "TO," were combined to constitute "TR" (Tuberculin rest), which is really an emulsion of minute fragments of cells. It is readily absorbed and does not cause the formation of abscesses. This is commonly called Koch's new tuberculin. Still another preparation which Koch has recently devised for active immunization and for convenience in performing the agglutination test consists of dried and ground up bacilli which are suspended in equal parts of glycerin and water, *Neutuberculin* Koch (*Bazillenemulsion*). The immunizing value of these preparations will be considered in the next number of The Journal.

Other Tuberculins.

Preparations which in many respects are analogous to those of Koch have been made by different investigators: the tuberculocidin of Klebs, the tuberculins of de Schweinitz and Dorset and that of Denys, the two toxins or tuberculins of Maragliano, which he utilizes for the preparation of antitoxic serums, the oxytuberculin of Herschfelder, the "TD" and the "TDR" of Behring and the tuberculoplasmin of Buchner. Marmorek claims to have produced the true toxin of the tubercle bacillus by growing young, vigorous cultures on a complicated medium, denying that tuberculin represents the true toxin of the organism.

Standardization.

Tuberculin can not be standardized with accuracy. From the fact that tuberculous animals are extraordinarily susceptible to injections of tubercular preparations Koch decided to estimate the value of tuberculin by determining its fatal dose when injected in tuberculous guinea-pigs. From 0.5 to 1 c.c. of tuberculin, when injected into a healthy guinea-pig, causes neither a local nor a general reaction, whereas from 0.1 to 0.15 c.c.

is time enough for the formation of cicatricial retraction. Dr. Freer has examined a number of his earliest patients, but in none of them was there the slightest evidence of sinking in of the nasal profile or of any cicatrix in the septum whatever. Instead of that, in all of these cases there was a complete or nearly complete replacement of the firmness of the septum. If a cicatrix were going to form it would surely begin to show some of its evil effects in the course of the four years that have passed since his first operation, for scars in the other parts of the body are not so slow in creating retraction, and at least some cicatricial drawing in of the mucosa of the septum would be seen, yet he has never observed anything resembling it. A large perforation, as suggested, would make the nasal chambers unduly roomy and lead to crusting on its edges. Dr. Freer has never seen sinking in of the nasal profile as *an immediate or early result* of the operation. He has often resected the cartilage from its free border to the bony septum, and as high as the perpendicular plate, and has never seen sunken noses as a consequence, even in the least degree. Killian, with his great material, reports no such *deformity. Mueller and Menzel*, however, mention slight sinking in of the profile in a few cases, and think it due to resecting the cartilage too closely under the triangular cartilages of the external nose; that is, directly under the nasal bridge. Dr. Freer suggested in his article that a narrow strip should be preserved in order to be in accord with their experience, although it is unique. The submucous resection is an operation for the rhinologist, requires the proper outfit and above all rhinologic skill, and is not for the general surgeon. It would be surprising if Dr. Myles had not thought out the principles of the window resection long ago, as he has thought out most of the things we think new, and he has certainly established his claims to be among the first by the reprint he has shown us to-day. Dr. Freer called attention to another misleading remark often made, that the mucous covering may be peeled from the deflection as easily as the rind from an orange. It peels off easily very often, but just as often does not, and it is in these adherent cases that minute, careful dissection is needed to avoid a perforation.

CHAPTER XXVII.

TUBERCULOSIS.

Tuberculosis is as old as the history of medicine, and its contagiousness was assumed but not demonstrated at a very early period. Klemke in 1843, but more particularly Villemin in 1865, demonstrated the infectiousness of tuberculosis by animal experiments, and these results were substantiated later by such investigators as Klebs, Chauveau, Baumgarten and Conheim. As the era of specific microbic etiology developed search for the germ of tuberculosis began and for a period a number of organisms were erroneously considered as the cause. Of these the *Monas tuberculosum of Klebs obtained* considerable prominence. Baumgarten first saw the tubercle bacillus in sections of tubercular material from which the tissue cells had been dissolved by potassium hydroxid, and at almost the same time Koch succeeded in demonstrating its presence in all tubercular lesions by a special staining method. He eventually obtained the organism in pure cultures with which he again produced tuberculosis in experiment animals.

Characteristics of the Bacillus.

The tubercle bacillus is an obligate aërobic parasite, has the form of a slender, *non-motile*, non-flagellated rod, often slightly curved, from 2 to 4 microns long and from 0.3 to 0.5 microns broad. In stained and even in unstained specimens, when properly treated, a number of spherical, oval *or elongated* clear spaces can be seen which at one time were thought by Koch to be spores. They are now considered either as vacuoles, or as representing some form of degeneration or reserve nutritious material. True spores have not been positively demonstrated, although their existence is upheld by some observers. The organism is supposed to possess a membrane which may be responsible for the rather strong resistance against heat and desiccation which the bacillus manifests. Feinberg speaks of a nucleus which may be demonstrated by a modified Romanowsky stain. The organism shows many variations in its morphology under different conditions. It often exists in isolated clumps, either in cultures or in tissues, and may be excreted as such in the urine. In certain cultures and sometimes in animal tissues it grows *in the form of longer or shorter branching* threads, in this respect resembling the actinomyces. This last occurrence has led a number of authorities to class the tubercle bacillus as a streptothrix, while others would give it an intermediate position between true bacteria (schizomycetes) and the streptothrix (a hyphomyces). An oval or spherical degeneration form of the organism is found in advanced tuberculosis of the lymph glands and other organs in which there is a great deal of necrosis. These have been called the capsules or, more properly, the corpuscles, of Schrön.

Staining Properties.

The tubercle bacillus is one of a group of organisms which are said to be "acid fast" in their staining properties. When stained with the carbol fuchsin of Ziehl and subjected to the action of mineral acids in dilute solutions the fuchsin is not removed. After this treatment it is customary to counterstain with an alkaline solution of methylene blue. In such a preparation the tubercle bacilli appear red, whereas other organisms which are not "acid fast" are stained with the methylene blue. It is not difficult to recognize the bacilli in sections of tissue when the proper technic is used, although the search is at times a laborious one. In old processes the organism often can not be recognized, and recourse to animal inoculation may be necessary in order to demonstrate the existence of tuberculosis.

Pure Cultures and Culture Media.

It is ordinarily a difficult technical problem to obtain the tubercle bacillus in pure culture, the technic of which we need not consider. Even under the best conditions growth is very slow, and may not be recognizable *to the naked eye for from six to ten* days. Coagulated serum of the cow to which has been added from 2 to 4 per cent. glycerin is the most favorable culture medium. Good growth occurs also in glycerin agar and in glycerin bouillon and on potatoes. The optimum temperature is 37 C.; growth does not occur above 42 nor below 30 C. When a small amount of culture is planted on the surface of the glycerin bouillon it proliferates slowly to form a heavy membrane which extends over the surface. In time this growth sinks from its own weight and a new membrane forms. This process continues until large masses have accumulated at the bottom of the flask.

Resistance.

The organism is very resistant to desiccation, living approximately three months in dried sputum. Only spore-forming organisms exceed the tubercle bacillus in their resistance to desiccation. Sputum appears to give it a certain protection against desiccation and light. Direct sunlight destroys it in a few hours at the most, whereas diffuse light kills it only after *from five to seven days* (Koch). It is said that the guinea-pig when exposed to sunlight withstands tuberculosis for a longer time than one which is kept in the dark. Roentgen rays are bactericidal for the organism, killing it in about one hour (Rieder). Under moist heat a temperature of 55 C. kills it in from four to six hours, 60 C. in one hour, 70 C. in *from ten* to twenty minutes, 80 C. in five minutes, from 90 to 95 C. in from one to two minutes. When embedded in sputum it is more resistant, five minutes being required to kill it at the boiling temperature. Corrosive sublimate is not a good disinfectant in this case, inasmuch as it produces an albuminous precipitate around the organism which prevents penetration of the sublimate. Five per cent. carbolic acid added to equal parts of sputum kills the bacillus in twenty-four ho
Formalin vapor is a *good* disinfectant for dry, but not
moist sputum. Iodoform is not a good disinfectant, in
of its beneficial influence on the infectious process. The
sistance of the bacillus to gastric digestion has an impo
bearing on the occurrence of infection in the intestinal tr

the ala against the cartilage. These patients become accustomed to contracting muscles of the side and front of the face for the purpose of pulling the ala away from the cartilage. Others sleep with the hand on the cheek, instinctively elevating the ala. This condition, Dr. Myles said, may be overlooked, especially when the nasal septum is involved, consequently it is well to test the inspiratory capacity with the mouth closed and with each nostril respectively closed. Dr. Myles said that he has had little success in attempting to replace the cartilage by fracturing the convex cartilage in the opposite nostril and then keeping the fragments in apposition with mechanical appliances until union takes place, and described the method of procedure in detail with the instruments used. He stated that in the majority of cases the wounds heal by first intention and that the after-treatment consists in filling the vestibule with aseptic cotton and leaving it in place for from two to three days. The results, he said, are beneficial in a respiratory sense; the appearance is much improved and a decided improvement is noted in the quality of the voice. Another form of stenosis which ought to be considered, Dr. Myles said, is caused by a deflection and circumscribed growth or enlargement on the convex side of the triangular cartilage; this also can be relieved by this method of subperichondrial dissection.

Dr. Otto T. Freer, Chicago, said that the head mirror gives rays parallel to the axis of the eye looking through the hole in the mirror, as well as does the Kirstein light, but he stated in the paper the use of the head mirror implies a light to reflect from, which dazzles the operator and limits the freedom of motion of his head. The Kirstein light, though not a necessity to the operation, permits more accurate work than does the head mirror, for it enables the surgeon to approach his eyes closely as he wishes to the operative field, so that even a presbyopic individual by the use of strong convex spectacles can get a magnified image of the details of the naris. This is of especial value in operating in the little nostrils of children. With the head mirror Dr. Freer is not able to get nearer to the work than 12 inches; with the Kirstein light he can approach to five when he wishes to look closely. Operators who are presbyopic or hypermetropic should always see that they have strong enough glasses before beginning the resection. He always uses the right hand for operating. Ambidextrous persons have an advantage here. Dr. Freer has often seen the firmness of the septum restored, but he can not state whether it was made so by hyaline cartilage, as a histologic examination was of course not possible. In children, the solidity of the septum is reproduced in a few weeks because of the great formative energy of their tissues. He agrees with Dr. Welty that the method of Menzel and Hajek is less elaborate. The question is, does it accomplish the object as well? Is it an advantage to confine oneself to a few instruments, and are such simple implements well adapted to fit all types of a deformity presenting such great variations in form, degree and difficulty as does deflection of the septum? The method of Menzel favors perforations, and what is worse, incomplete operations on the bony part of the deflection. In addition, by beginning always at the front from the free border of the septum, a certain amount of perfectly straight septal cartilage is sacrificed in order to reach deflections beginning deeper in the nose, an objection to Menzel's procedure urged by Weil. The elevators known as Hajek's in this country are used in the Menzel operation, and have been extensively introduced here. Dr. Freer admitted that they are few and simple, in fact only two, but they are thick and clumsy and too large for deflections. They would fill the nostril of a child, and one often has to operate on children. A thick, blunt elevator, like Hajek's blunt one, is liable to plunge through where the mucosa is adherent, because force is necessary to undermine with thick implements. Menzel's method is well adapted to certain cartilaginous deviations where the separation is easy, but not to difficult resections where there is much adhesion of mucosa or where the bony septum is involved. All the German methods of performing the window resection are marked by a certain roughness. German authors speak of breaking out of bone and cartilage with dressing forceps; in fact, Mueller attributes some slight depressions of the nasal bridge he mentions as due to his having broken out cartilage under it. The cartilage should always be cleanly cut away and never broken or twisted out. Dr. Freer said that he has heard before the assertion that the operation may be done with a few simple instruments that do not even need to be specially made for it, for the man is always with us who thinks that he can do offhand with his jack-knife what others accomplish by taking pains with proper tools. Some kinds of rough wood work may be done with an ax, but if Dr. Freer wanted finely finished cabinet work he employs an artisan who has a full set of tools; planes, chisels, squares and everything. Those unfamiliar with the operation should not be deceived into thinking that it is so simple in every instance that the use of instruments especially fitted for the purpose may be safely discarded. Those so poorly equipped will be apt to abandon the operation after encountering a few difficult cases or else will get the proper outfit for the work. The chief reason for a larger instrumentarium is that there are odd intricate cases that require odd instruments. He fashioned his original blades from steel forms on small grinding wheels, run on an electric lathe. According to the lessons taught him by cases as they arose, he changed his models until they reached a state which required no further alteration. A special feature of his instrumentarium, permitting rapid and neat work, is the presence of a number of keen thin blades for dissection, a feature lacking in many other collections of instruments; their devisors seeming to have the forcible pushing off of the mucosa from its attachment chiefly in mind. Keen dissection is, however, constantly required, because of the frequency of adherent places. Scissors he does not regard as at all adapted to the work, and he never uses the saw. In reply to a question about general anesthesia, he said that he has never used it for adults nor for children over 11. For children of 11 or younger he uses just enough chloroform to make them unconscious of their surroundings, but relies on the cocain local insensibility to subdue pain. Dr. Freer said that Dr. Richards' experience in respect to spells of faintness is not in accord with his. Though he has never had a patient in actual syncope from sitting up, he has had a number come close to it, and so thinks it preferable to do most of the work with the patient lying down. He can see no reason for trying to make the operation a speedy one at a sacrifice of exactness. The patient does not suffer, and haste means careless work and perforations. He requires from one-half to one and one-half hours, according to the difficulties met, and can not understand the statement of Killian that he completes his operation in the average time of twenty minutes, nor how any one can radically and neatly resect deflections in such a rapid manner. He agreed with Dr. Cott that in most cases the danger of spontaneous bleeding is over in twenty-four hours, but if the packing be removed at this early period it is apt to start a fresh traumatic hemorrhage, because the tampon still adheres to the mucosa, while by the fourth day it is covered with slippery mucus and may be pulled out readily. He has had some very exciting times in the few cases in which he allowed himself to pack loosely, profuse delayed hemorrhage occurring a few hours after the operation, so that he is not satisfied now unless the packing be even and firm. He has had no bleeding since he has used my present method of tamponing. He thinks it reckless not to pack at all, and strongly advises against it. He has never needed to tampon the nasopharynx while operating. What little blood escapes the swabs and flows back into the nasopharynx is swallowed unnoticed by the reclining patient. He used the dental engine a great deal in his earlier work, but since he has new bone-cutting forceps he has practically discarded it. The trephine works more or less in the dark, is hard to control, tears up the mucosa and bores into unknown depths in a way that is uncanny. The burr he finds less efficient than the trephine. Dr. Freer said that he is sorry that such theories as the possibility of depressed nasal bridges and formation of cicatricial tissue in the septum are being raised to delay the advance of a method that removes all deflections so certainly and with so little injury to the patient as does the submucous resection. The purely fanciful objection made is not borne out by any recorded experience, in spite of the fact that Krieg reported his first window resections in 1886, nineteen years ago. Surely, that is time enough for the formation of cicatricial retraction. Dr. Freer has examined a number of his earliest patients, but in none of them was there the slightest evidence of sinking in of the nasal profile or of any cicatrix in the septum whatever. Instead of that, in all of these cases there was a complete or nearly complete replacement of the firmness of the septum. If a cicatrix were going to form it would surely begin to show some of its evil effects in the course of the four years that have passed since his first operation, for scars in the other parts of the body are not so slow in creating retraction, and at least some cicatricial drawing in of the mucosa of the septum would be seen, yet he has never observed anything resembling it. A large perforation, as suggested, would make the nasal chambers unduly roomy and lead to crusting on its edges. Dr. Freer has never seen sinking in of the nasal profile as an immediate or early result of the operation. He has often resected the cartilage from its free border to the bony septum, and as high as the perpendicular plate, and has never seen sunken noses as a consequence, even in the least degree. Killian, with his great material, reports no such deformity. Mueller and Menzel, however, mention slight sinking in of the profile in a few cases, and think it due to resecting the cartilage too closely under the triangular cartilages of the external nose; that is, directly under the nasal bridge. Dr. Freer suggested in his article that a narrow strip should be preserved in order to be in accord with their experience, although it is unique. The submucous resection is an operation for the rhinologist, requires the proper outfit and above all rhinologic skill, and is not for the general surgeon. It would be surprising if Dr. Myles had not thought out the principles of the window resection long ago, as he has thought out most of the things we think new, and he has certainly established his claims to be among the first by the reprint he has shown us to-day. Dr. Freer called attention to another misleading remark often made, that the mucous covering may be peeled from the deflection as easily as the rind from an orange. It peels off easily very often, but just as often does not, and it is in these adherent cases that minute, careful dissection is needed to avoid a perforation.

CHAPTER XXVII.

TUBERCULOSIS.

Tuberculosis is as old as the history of medicine, and its contagiousness was assumed but not demonstrated at a very early period. Klemke in 1843, but more particularly Villemin in 1865, demonstrated the infectiousness of tuberculosis by animal experiments, and these results were substantiated later by such investigators as Klebs, Chauveau, Baumgarten and Conheim. As the era of specific microbic etiology developed search for the germ of tuberculosis began and for a period a number of organisms were erroneously considered as the cause. Of these the *Monas tuberculosum* of Klebs obtained considerable prominence. Baumgarten first saw the tubercle bacillus in sections of tubercular material from which the tissue cells had been dissolved by potassium hydroxid, and at almost the same time Koch succeeded in demonstrating its presence in all tubercular lesions by a special staining method. He eventually obtained the organism in pure cultures with which he again produced tuberculosis in experiment animals.

Characteristics of the Bacillus.

The tubercle bacillus is an obligate aërobic parasite, has the form of a slender, non-motile, non-flagellated rod, often slightly curved, from 2 to 4 microns long and from 0.3 to 0.5 microns broad. In stained and even in unstained specimens, when properly treated, a number of spherical, oval or elongated clear spaces can be seen which at one time were thought by Koch to be spores. They are now considered either as vacuoles, or as representing some form of degeneration or reserve nutritious material. True spores have not been positively demonstrated, although their existence is upheld by some observers. The organism is supposed to possess a membrane which may be responsible for the rather strong resistance against heat and desiccation which the bacillus manifests. Feinberg speaks of a nucleus which may be demonstrated by a modified Romanowsky stain. The organism shows many variations in its morphology under different conditions. It often exists in isolated clumps, either in cultures or in tissues, and may be excreted as such in the urine. In certain cultures and sometimes in animal tissues it grows in the form of longer or shorter branching threads, in this respect resembling the actinomyces. This last occurrence has led a number of authorities to class the tubercle bacillus as a streptothrix, while others would give it an intermediate position between true bacteria (schizomycetes) and the streptothrix (a hyphomyces). An oval or spherical degeneration form of the organism is found in advanced tuberculosis of the lymph glands and other organs in which there is a great deal of necrosis. These have been called the capsules or, more properly, the corpuscles, of Schrön.

Staining Properties.

The tubercle bacillus is one of a group of organisms which are said to be "acid fast" in their staining properties. When stained with the carbol fuchsin of Ziehl and subjected to the action of mineral acids in dilute solutions the fuchsin is not removed. After this treatment it is customary to counterstain with an alkaline solution of methylene blue. In such a preparation the tubercle bacilli appear red, whereas other organisms which are not "acid fast" are stained with the methylene blue. It is not difficult to recognize the bacilli in sections of tissue when the proper technic is used, although the search is at times a laborious one. In old processes the organism often can not be recognized, and recourse to animal inoculation may be necessary in order to demonstrate the existence of tuberculosis.

Pure Cultures and Culture Media.

It is ordinarily a difficult technical problem to obtain the tubercle bacillus in pure culture, the technic of which we need not consider. Even under the best conditions growth is very slow, and may not be recognizable to the naked eye for from six to ten days. Coagulated serum of the cow to which has been added from 2 to 4 per cent. glycerin is the most favorable culture medium. Good growth occurs also in glycerin agar and in glycerin bouillon and on potatoes. The optimum temperature is 37 C.; growth does not occur above 42 nor below 30 C. When a small amount of culture is planted on the surface of the glycerin bouillon it proliferates slowly to form a heavy membrane which extends over the surface. In time this growth sinks from its own weight and a new membrane forms. This process continues until large masses have accumulated at the bottom of the flask.

Resistance.

The organism is very resistant to desiccation, living approximately three months in dried sputum. Only spore-forming organisms exceed the tubercle bacillus in their resistance to desiccation. Sputum appears to give it a certain protection against desiccation and light. Direct sunlight destroys it in a few hours at the most, whereas diffuse light kills it only after from five to seven days (Koch). It is said that the guinea-pig when exposed to sunlight withstands tuberculosis for a longer time than one which is kept in the dark. Roentgen rays are bactericidal for the organism, killing it in about one hour (Rieder). Under moist heat a temperature of 55 C. kills it in from four to six hours, 60 C. in one hour, 70 C. in from t to twenty minutes, 80 C. in five minutes, from 90 to 95 C. from one to two minutes. When embedded in sputum it more resistant, five minutes being required to kill it at boiling temperature. Corrosive sublimate is not a good infectant in this case, inasmuch as it produces an alk precipitate around the organism which prevents per of the sublimate. Five per cent. carbolic acid added to parts of sputum kills the bacillus in twenty-four h. Formalin vapor is a good disinfectant for dry, but not moist sputum. Iodoform is not a good disinfectant, in of its beneficial influence on the infectious process. The sistance of the bacillus to gastric digestion has an import bearing on the occurrence of infection in the intestinal

The gastric juice of the dog, in one instance, failed to kill it after six hours' exposure, although it had the power of prohibiting proliferation.

Virulence.

The bacillus of human tuberculosis, although fairly constant in its virulence, may be attenuated by various means. Its prolonged existence in putrid sputum decreases its virulence and a similar decrease occurs on potato, in old cultures or in those which contain iodoform, boracic acid and some other substances. Inoculation with such cultures produces a chronic form of tuberculosis in animals which may heal. In other instances cultures which have grown on artificial media for many years retained their original virulence.

The organism contains about 90 per cent. of water. One-fourth of a dried bacterial mass may be extracted as a wax-like or fat-like substance by a mixture of alcohol and ether. The acid-fast staining property of the bacillus depends on this substance. The remaining portion of the mass, consisting largely of proteins, which may be extracted by dilute alkalies, contains a toxic nucleo-albumin. Cellulose, representing a portion of the capsular substance, is also found in the residue.

Toxic Products.

Killed cultures when given subcutaneously produce necrosis, abscesses, caseation, marasmus, and a subnormal temperature. When given to rabbits and guinea-pigs intravenously they cause rapid emaciation and death in from a few days to a few weeks. By beginning with very minute doses, however, the animals may be gradually habituated to intoxication by the dead bacilli and eventually withstand large doses. The same holds true of the various toxic substances, including tuberculin, which may be extracted from cultures. The proteins and alkaline extracts cause abscesses when given subcutaneously. The fever-producing substance which is present in the preparations mentioned below is one of the metabolic products of the bacillus, rather than a constituent of the bacterial cell (Koch). This substance is 100 times as toxic for tuberculous animals as for healthy and causes an increase in the eosinophiles of the blood. In addition to the fever-producing substance, Maragliano and others recognize as a constituent of the bacillus a heat susceptible "toxalbumin" (destroyed at 100 C.) which reduces temperature. Hammerschlag speaks of a toxin which in animals causes fatal convulsions. The toxic products of the tubercle bacillus show their greatest toxicity when injected into the brain, and this method of injection has been suggested for the standardization of tuberculin.

Tuberculin.

Of the toxic preparations of the bacillus the greatest interest attaches to tuberculin which Koch, in 1891, announced as an agent which could be used for the specific diagnosis of tuberculosis and which, when properly administered, had certain curative effects. Its preparation is simple. Cultures are allowed to grow for four weeks in peptone bouillon which contains 5 per cent. of glycerin. At the end of this time the organisms are killed by exposure to a temperature of 100 C. for one hour (Marx). The fluid is reduced to one-tenth its original volume by evaporation under a vacuum at a low temperature and the bacterial cells are eventually removed by filtration. The percentage of glycerin which is present in the final preparation acts as a preservative, but 0.5 per cent. carbolic acid may be added in addition. The active substance in tuberculin may be precipitated by 66 per cent. alcohol; its chemical nature remains unknown.

"TA" and "TR" Preparations.

In addition to the "old" tuberculin, which has just been described, Koch has prepared several variations of the substance, the use of which has been proposed for diagnostic and curative purposes and for convenience in carrying out the agglutination reaction. One of these, "TA," is an alkaline preparation which is made by extracting cultures with 1/10 normal sodium hydroxid solution. Its value as a diagnostic was equal to or exceeded that of tuberculin because of the longer duration of the reaction. In view of the fact, however, that it contained undissolved cells, which caused the formation of abscesses at the point of injection, its use was not encouraged. For purposes of immunization Koch prepared a fluid which contained all the bacterial constituents and which at the same time is readily absorbed without abscess formation. For its preparation dried masses of the organism are ground up in an agate mortar and after suspension in distilled water and centrifugation, the emulsion consists of two layers. The overlying opalescent whitish fluid was designated as "TO" (Tuberculin Obers). After removal of the fluid from the precipitate the latter was again dried and ground, suspended in water and centrifugated as before, and the process repeated until none of the sediment remained. The different fractions of fluid, except the "TO," were combined to constitute "TR" (Tuberculin rest), which is really an emulsion of minute fragments of cells. It is readily absorbed and does not cause the formation of abscesses. This is commonly called Koch's new tuberculin. Still another preparation which Koch has recently devised for active immunization and for convenience in performing the agglutination test consists of dried and ground up bacilli which are suspended in equal parts of glycerin and water, *Neutuberculin* Koch (*Bazillenemulsion*). The immunizing value of these preparations will be considered in the next number of THE JOURNAL.

Other Tuberculins.

Preparations which in many respects are analogous to those of Koch have been made by different investigators: the tuberculocidin of Klebs, the tuberculins of de Schweinitz and Dorset and that of Denys, the two toxins or tuberculins of Maragliano, which he utilizes for the preparation of antitoxic serums, the oxytuberculin of Herschfelder, the "TD" and the "TDR" of Behring and the tuberculoplasmin of Buchner. Marmorek claims to have produced the true toxin of the tubercle bacillus by growing young, vigorous cultures on a complicated medium, denying that tuberculin represents the true toxin of the organism.

Standardization.

Tuberculin can not be standardized with accuracy. From the fact that tuberculous animals are extraordinarily susceptible to injections of tubercular preparations Koch decided to estimate the value of tuberculin by determining its fatal dose when injected in tuberculous guinea-pigs. From 0.5 to 1 c.c. of tuberculin, when injected into a healthy guinea-pig, causes neither a local nor a general reaction, whereas from 0.1 to 0.15 c.c. kills a tuberculous guinea-pig in from twenty-four to forty-eight hours. This phenomenon will be considered later in connection with the so-called agressins of Bail. For standardization von Lingelsheim recommends intracerebral injection into healthy guinea-pigs, because of the extreme toxicity of tuberculin when introduced into the central nervous system; only 1/180 as much tuberculin was required to cause death by intracerebral injections as compared with subcutaneous or intraperitoneal. Behring bases the value of tuberculin on its toxicity for healthy guinea-pigs and in his terms the expression " 1 c.cm. = 1,000 M." means that one gram of the toxin is fatal to 1,000 grams of guinea-pig tissue. His "TD" has a value of 1,250 M., and "TDR," 12,500 M.

(To be continued.)

Clinical Reports

CASE OF EXTREMELY LONG PREGNANCY.

J. ARTHUR LAMB, M.D., C.M.
KALISPELL, MONT.

I have had an exceptional opportunity for obtaining accurate data in a case of long pregnancy, and later, of finding what seemed to be the probable cause.

Patient.—Mrs. T., aged 46, height 5 feet 5 inches, weight 155 pounds.

Previous History.—The patient has always enjoyed good health; she has had nine normal confinements, her oldest child being 23 years old, the youngest 5 years, all living; she never had a miscarriage and never vomited except when pregnant. She has always vomited for the first three months of pregnancy, and has never been more than a week out in the expected date of confinement. Menstruation was always regular till the last child was born, since which time she has occasionally missed one or two periods, which she thought was due to a change of life.

History of Pregnancy.—June 29, 1904, she commenced vomiting, and a few days later menstruation failed to appear. July 1, 1904, her husband, whose work called him to Idaho, left here, and did not return till sometime after the confinement. When he left both patient and husband considered that she was pregnant. During the entire pregnancy she lived here with her seven children. The last menstruation commenced June 5, 1904, and lasted till June 9. Vomiting commenced June 29, 1904, and lasted till March 1, 1905. Fetal movements were first felt Oct. 15, 1904.

Examination.—About April 1, 1905, she began to worry about going overtime and sent for me. Examination showed appearance of full term; child in L.O.A. position; fetal heart in left iliac region, 132 beats to the minute; movements very active. Patient's urine was normal.

Further History.—I left her, assuring her that there was no cause for worry, and as far as I could make out everything was all right. During April I heard from her frequently, and told her to take considerable exercise in the open air, hoping that this would start up the pains.

On May 8, 1905, I made another examination and the following notes: "Uterus quite large, fetal heart in left iliac region, 132 beats; position of child L. O. A.; movements very active; head above brim. At the external os, two rounded masses are felt which seem to be attached to the cervix."

By this time I was becoming anxious about letting the case go any longer, as the uterus was very large. The patient was also getting tired of waiting, so I promised if labor did not start by next day, to induce it. As nothing had happened by next day, I prescribed capsules of quinin sulphate grs. 5, one every four hours, and after taking four, the pains started.

Labor.—The first stage of labor started at 12:15 a. m., May 10, 1905. At 2:15 a. m. the water broke (moderate in amount), and at 2:30 a. m., when I arrived, the pains were quite strong and frequent.

During the second stage, while the head was coming down, and while I was making an examination, I felt two masses (which I had noticed at a previous examination) descending. I then realized that some abnormal condition was present, and were it not that the position of the child had been made out so plainly previously, I could easily understand how a snap diagnosis of breech presentation (these masses felt exactly like testicles) could have been made. At 4 a. m. an anencephalic monster was born. The masses which had puzzled me now proved to be the exposed brain. The third stage terminated at 4:30 a. m., May 10, normally, no laceration or hemorrhage occurring. The puerperium was normal in every respect.

Description of Child.—The child was a large male, well developed in every respect except its head. One hour before birth the fetal heart was distinctly heard, and the movements were very active, but when the child was born no attempt at respiration was made.

The following measurements and observations were made: Length, 22½ inches; weight 10 pounds (appeared much heavier); circumferences: bisacromial, 16 inches; bistrochanteric, 14 inches. The placenta was large, oval, 1½ pounds and normal in every respect. The cord was 36 inches long, of moderate volume, no knots and apparently normal.

Remarks.—The cause of the prolonged pregnancy in this case may have been partly due to patient's age, 46, and the number of previous pregnancies producing uterine sluggishness, but the peculiar condition and shape of the head, preventing engagement and suitable pressure on the os uteri, probably had more to do with it. It might have been interesting to have known how long this case would have gone had no quinin been given to cause uterine contractions.

Summary of Duration of This Case.—From commencement of last menstruation, June 5, 1904, 339 days; from last intercourse, July 1, 1904, 313 days; vomiting lasted from June 29, 1904, to March 1, 1905; quickening occurred Oct. 15, 1904; confinement occurred May 10, 1905.

Dr. Robert [illegible] Library

A CASE OF SO-CALLED "MUSICAL HEART."

JOSEPH M. PATTON, M.D.
CHICAGO.

The case here reported is of unusual interest because of its rarity and because of the fact that, during a period of about fifteen years previous to death, the patient had been observed and examined by probably a greater number of physicians and students than any other individual of which we have record. During this period he made a living principally by posing for purposes of demonstration before medical classes, both undergraduates and postgraduates, and on one or two occasions was on public exhibition as "the man with the musical heart."

Patient.—The patient was 38 years old at death. According to his statement he was of Russian birth and had been exiled to Siberia, but had escaped and emigrated to America about fifteen years ago. Shortly after reaching this country, and while in New York City, he suffered from inflammatory rheumatism and entered Bellevue Hospital. It was while in this institution that the peculiar murmur, which was afterward studied by so many physicians, was discovered, and presumably it was developed at that time, at least there appears to be no evidence to the contrary. My personal knowledge of the patient dates back about twelve years, when he appeared at my clinic for the first time. He carried a number of written diagnoses, some of which were more or less fanciful and presupposed all manner of lesions of either the right or left sides of the heart or both. The patient himself claimed that his heart had been wounded by a sword thrust. There was, indeed, a scar on the chest wall about two inches below the nipple, but this scar was entirely superficial, and it was not apparent that, whatever the cause of the injury, it could have had anything to do with the cardiac state.

Examination.—Examination at this time determined an hypertrophied and dilated heart. The impulse was heaving and diffuse, and its area was markedly increased. The apex impulse was under the seventh rib, about two inches to the left of the mammillary line. The cardiac rhythm was somewhat irregular. Auscultation determined double mitral and double aortic murmurs. The mitral presystolic murmur was short and ill defined, while the regurgitant exhibited the usual characteristics. The aortic regurgitant murmur showed the ordinary quality and area of distribution, but the obstructive murmur was only to be distinguished above the first rib, because of the greater prominence of the systolic musical murmur which constituted the unique feature of the case. This murmur was a distinct musical note occurring with the cardiac systole and heard all over the precordial area, but plainest from the second rib to the fifth interspace along the left parasternal line. It was not transmitted in any particular direction, but was gradually lost as the distance from the area of the greatest intensity increased. The pitch of the sound varied, at times being high and sharp, and again being lower and more sonorous. The length of a murmur also varied considerably. At times the sound could be heard with the ear close to, but not in contact with, the chest wall, and at other times the sound could not be heard unless the ear was in contact with the chest wall. The patient suffered no special inconvenience as long as he did not exert himself.

Diagnosis.—The diagnosis at that time was double aortic and double mitral lesions, and a musical murmur originating in the left ventricle and probably due to some abnormal condition of the chordæ tendineæ.

Subsequent History.—The patient was observed at intervals ever since, and until the past winter there appeared to be little change in his condition. In February last he appeared at my office complaining of being ill and stating that a short time before the musical murmur had disappeared. It was over the latter fact that he was specially concerned, and he was much cast down when I told him that it was not probable that the murmur would return. He was suffering from an acute bronchitis of the base of the lungs and had a temperature of 102 F. He was sent to the Policlinic Hospital and remained there a week. His heart at this time was dilated and the mitral and aortic regurgitant murmurs were the only ones to be heard. He improved under treatment and left the hospital. A month or so later he appeared at my office with temperature, cough and dyspnea, and he had evidently lost strength. The bronchitis had not cleared up and his heart was acting badly. He would not go to bed or stay in the house. His last visit to my office was on May 26. He died on the night of May 30. I did not see him in the interval.

Autopsy.—The postmortem, which included the heart only, was made by Dr. John Fisher. There was a moderate amount of fluid in both pleural spaces and in the pericardial sac.

Heart: The examination of the heart was made early the following morning by Dr. Fisher and myself, and disclosed the following conditions:

Weight of heart	19 ounces.
Wall of left ventricle	25 mm. thick.
Wall of right ventricle	6 mm. thick.
Wall of left auricle	3 mm. thick.
Wall of right auricle	2 mm. thick.
Length of cavity of left ventricle	90 mm.
Length of cavity of right ventricle	65 mm.
Left auricle much dilated.	
Mitral opening, oval	37x22 mm.
Aortic opening somewhat triangular	20x15 mm.
Tricuspid opening,	45 mm.

The mitral valves were markedly vegetative, the anterior cusp being unusually long and covered with coarse vegetations (Fig. 1). Its edges were deeply serrated. Two chordæ tendineæ which were attached to the tip of the anterior cusp and to the papillary muscle at the apex of the ventricle were thickened and covered with fine vegetations. Their valvular attachment was broken and they floated loose in the cavity of the ventricle, being attached only to the papillary muscle. The aortic valves were retracted by curling and thickening of their edges (Fig. 2). From the corners of the base of the cusps, on their aortic surface, there are short cords about the thickness of chordæ tendineæ, from one and a half to two centimeters long, which attach the base of the cusps to the vascular wall. Anteriorly there are two of these cords, posteriorly and to the right there are two, and posteriorly and to the left there are three. A communication exists between the right auricle and the base of the left ventricle, the auricular opening being near the base of the posterior cusp of the tricuspid valve, and the ventricular opening being between the base of the left cusp of the aortic valve and the base of the anterior cusp of the mitral valve (Fig. 3). This opening admits a match, but its auricular orifice is closed by a papilla which acts as a valve.

Summary.—The gross findings in this case are those of double lesions of the mitral and aortic orifices. Concerning the production of the musical murmur, there are only three factors to be considered in view of the integrity of the auricular and ventricular septa. These factors are the connection between the right auricle and left ventricle, the cord-like attachments to the arterial surface of the base of the aortic valve cusps, and the thickened chordæ tendineæ, whose attachment to the mitral valve had been broken. It is hardly conceivable that either of the two former could be of importance in this connection, because it is not evident that there was much or any current through the opening between the right auricle and the left ventricle, or that the adventitious cords in such a situation could possibly be connected with the production of such a long, high-pitched sound. Again, these conditions were still present after the murmur had absolutely disappeared, the heart action meanwhile being relatively good. The sudden disappearance of the murmur before the heart showed serious signs of failure can only be explained by the breaking of the valvular attachments of the chordæ tendineæ, which were involved in the inflammatory process. The greater tension of these cords during systole, which would be the result of their thickening, might easily result, with a cord of such length, in the production of a high pitched and sustained tone as characterized the heart action in this case.

Whether we accept the views of Corrigan and of Chauveau of the origin of a murmur in the blood stream because of the vibration produced when blood enters through a narrow into a dilated portion of a blood vessel, or those of Heyncius that a murmur is due to the production of eddies in the widest portion of a vessel—and there appear to be no very great difference in the physical principles involved in these theo it is evident that we can not apply to the cause of the mur in this case the basic principle governing the prod of ordinary murmurs that they are primarily vibratio the blood stream. The pitch of this murmur, and its har element as well, would require a degree of tension not patible with the circulation of the blood stream, and on be found in some denser structure. These physical re therefore, bring us back again to these broken cords f explanation of this murmur.

If, then, we can not apply to the cause of these disti musical murmurs (I employ the qualification here in co distinction to the harsh, almost musical sounds at times duced in cases of aortic or mitral obstruction), the ph of the ordinary bellows murmur of the heart, and assume they necessitate the rapid vibration of some of the orga structures of the heart itself, we must admit that they also a different prognosis. Musical murmurs, as a rule, a much more serious import than ordinary blowing mur In several instances I have observed their appearance in ous cases of endocarditis at varying periods before a termination. In one case of ulcerative endocarditis invo both aortic and mitral orifices a pronounced musical sy murmur developed a few days before death. This sound so loud that it could be heard distinctly at a distance of or five feet from the patient's chest.

An important deduction to be drawn from this case is musical murmurs of this character indicate a more exte degree of involvement of the tissues of the heart than is essary for the production of the ordinary blowing murmu

FASCIOLOPSIS BUSKII (DISTOMUM BUSK

THE FIRST REPORTED CASE IN THE UNITED STATE FOUND IN A PATIENT DYING OF TYPHOID FEVER.*

JOHN T. MOORE, M.D., AND J. J. TERRILL, M.D.
GALVESTON, TEXAS.

Attention has been called by one of us[1] to the possib of finding many of the parasites of tropical countries we systematically to look for them. We are pleased to sent a specimen of a rare intestinal parasite, in fact the recorded case of this fluke occurring outside of Asia, acc ing to Stiles,[2] from whom we have gained the most of knowledge of this fluke.

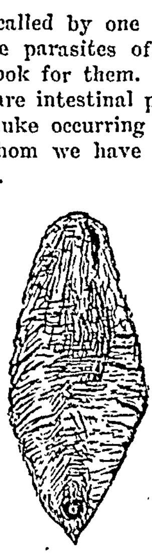

Fig. 1.—*Fasciolopsis buskii.* Original observation. Natural s Length, 4 cm. Width 1.6 cm.

History of Case.—The parasite was found in the intest of a Laskar who was sick aboard an English steamer in t port, and who was removed to the St. Mary's Infirma where Dr. Moore saw him. The case was diagnosed as pr ably typhoid fever, but as he died the following day the di nosis was not confirmed until it was done by postmorte The specimen of parasite was found in the intestine wh doing the postmortem, and along with the fluke we found large *Ascaris lumbricoides*. The fluke is of interest on accou

of its rarity and the possibility of having it introduced into our own country.

Classification.—This parasite belongs to the class known as trematodes and is the largest of the distomes hitherto found in man. The infection by any of the trematodes is known as distomatis, though Stiles says that the term distoma has been suppressed.

These trematodes may be found in different parts of the body and are accordingly classed as follows: 1, Ophthalmic; 2, cerebral; 3, pulmonary; 4, hepatic; 5, pancreatic; 6, intestinal; 7, venal, distomatosis.

The parasite we have under consideration is one of three that are found in the intestines of man, viz.: 1, *Fasciolopsis buskii;* 2, *Fasciolopsis rathouisi;* and 3, *Heterophyes heterophyes.* The first and second are found in Asia and the latter in Egypt and Japan.

Busk discovered this fluke in man in 1843, and all of the reported cases heretofore have been from Asia. As Stiles suggests, it is not known whether these trematodes could be distributed in this country or not, as it is known to require particular species of snails to act as intermediate hosts. All of the conditions may be present in this country, and if so, then it would be possible to introduce and spread the parasite here, and consequently its recognition becomes an important matter.

We shall use the generic and specific classification as given by Stiles,[2] which is as follows:

"Family Fasciolidæ—Genus *Fasciolopsis looss,* 1899.

"*Generic Diagnosis.—Fasciolidæ:* Body rather large, flat, about one-third as broad as long, lanceolate to tong-shaped. Cephalic cone wanting. Skin without spines. Ventral acetabulum larger than oral sucker and nearer anterior end. Intestine with short prepharynx, strong globular pharynx, and exceedingly short esophagus; intestinal ceca branch immediately anterior to ventral acetabulum, are narrow and long, extending along inner margin of vitellaria to the posterior end of the body, and are not provided with secondary branches. Excretory system similar to that of *Fasciola.* Genital pores empty into genital sinus, which is situated in the ventro-median line immediately anterior to acetabulum. Copulatory organ present, the cirrus pouch being a long, straight median tube extending caudate to a point about half way between ventral acetabulum and shell gland. Male organs: Testicles in the posterior half of median field, side by side, or one posterior to the other, both branched dicotomously. Female organs: Ovary moderately developed, branched, located at equator, right of median line; receptaculum seminis absent; Laurer's canal present; vitellaria well developed, with very small acini, and extend from plane of ventral acetabulum to caudal pole of body, where the acini from the two sides may meet in the median line; transverse section of body shows acini to be superficial both dorsally and ventrally; transverse vitello-ducts meet in median line of equator to form the vitelline reservoir; shell-gland compact, well developed, globular; uterus extends from equator forward, with lateral coils, and leads to the well-developed *metraterm* at caudal border of acetabulum. Eggs rather numerous, similar in form to those of *Fasciola.*

"*Habitat.*—Intestine of mammals.

"*Type Species.—Fasciolopsis buskii* (Lankester, 1857).

"Busk's Intestinal Fluke—*Fasciolopsis buskii* (Lankester, 1857) Stiles, 1901—of Man.

"*Specific Diagnosis.*—Fasciolopsis: 24 to 37 mm. (75 mm. after Busk) long, 5.5 to 12 or 14 mm. broad, 1.5 to 2 mm. thick; maximal breadth in equatorial portion; more attenuate anteriorly than posteriorly; ventral surface flat; dorsal surface slightly convex; margins very thin. Oral sucker ventro-subterminal small, 0.5 mm. in diameter, 0.33 mm. deep. Ventral acetabulum 1.6 to 2 mm. in diameter, but elongated caudally directly under the ventral surface in a 2 to 8 mm. long sack; center of acetabulum 1.8 to 2 mm. from anterior end of body. Skin without spines. Prepharynx 0.28 mm. long; pharynx, 0.7 mm.; esophagus very short, bifurcation of the intestine occurs about on anterior plane of acetabulum; ceca with two characteristic curves toward median line, one at equator, the other between the testicles.

"*Male Organs.*—Cirrus pouch cylindrical, median, nearly one-fourth as long as the body, 0.25 to 0.33 mm. thick, straight, extending from genital pore to about midway to shell gland (equator); it contains a long sinous vesicula seminalis with a long blind sack possessing lateral branches, this sack reaching from a short distance caudad of acetabulum to about 0.5 mm. from caudal end of pouch; pars prostatica 0.5 mm. long; ductus ejaculatorious rather short, provided with fine spines; vasa differentia near median line; testicles one posterior to the other; branches of posterior testicle extend to within about 3 mm. of the caudal end of the body. Female organs: Vitelline reservoir rather small; shell gland 1 to 1.5 mm. in diameter. Eggs numerous, 120 to 130 microns long by 77 to 80 microns broad. Sporocyst, redia, cercaria and intermediate host undetermined.

"*Habitat.*—Small intestine of man (*Homo sapiens*); Asia."

Specimen.—The specimen as shown in Figure 1 corresponds in every way to the above description. Before the fluke was placed in the hardening solution it assumed a variety of shapes, assuming almost an oval outline and then straightening out and narrowing itself very much. The movements, while not progressive, were rather active. Figure 3 is from a micro-photograph and corresponds to the section published by Stiles (after Odhner) on page 41 of his monograph.

The Ova.—The ova of this parasite were very numerous. They average 75 by 150 microns. They are oval in outline, are possessed of a double membrane, the two parts placed closely together with only a very narrow clear space between them. The outer wall is the thicker and more distinct. At one end is a distinct clear cap which by pressure may burst off and allow the contents to escape. Dividing the ovum into three almost equal parts are two transverse lines. We have found no mention of these lines in any of the former descriptions. They were present in all the ova examined except a few from which the contents had escaped. They are shown in Figures 5, 6 and 7. The contents are granular, with some small round clear spaces, and in some near the cap end is a round area about 10 microns in diameter which differs from the rest in appearing to have a very delicate membrane.

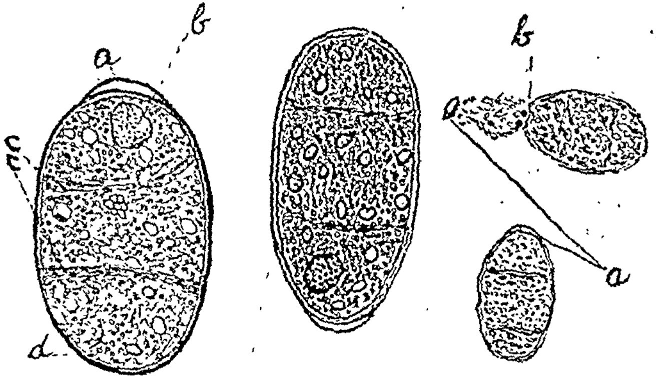

Fig. 5.—Ova of *Fasciolopsis buskii.* Original observations are drawings showing membranes, transverse lines, and cap. In one the cap is removed and contents are escaping. 75x150 microns. a, cap; b, opening in ovum; c, transverse markings.

Symptoms.—We are unable to say anything of these, as the case was not seen early enough. It is presumed though that persons thus infected must suffer from intestinal irritation, and possibly anemia.

Diagnosis.—The diagnosis is to be made by carefully examining the stools.

Treatment.—The ordinary anthelmintics should be tried.

We take this opportunity to thank Drs. R. C. Cabot and L. S. Brown of Harvard Medical School for the most excellent micro-photographs which are used to illustrate this paper.

Correction in Yellow Fever Article.—In the article on yellow fever in The Journal September 23, page 916, line 20, is a typographical error. The sentence should read "The described cells have only *once* been found after the third day," etc. We call attention to the error as it alters the meaning.

EXPERIMENTAL RESEARCHES ON CANCER.

Recently we commented on the report on the statistical investigations of cancer of the Imperial Cancer Research Fund of Great Britain. There has appeared since Part II of the same report, dealing with the growth of cancer under natural and experimental conditions. This report is of great importance, particularly because of the emphasis it places on the significance of experimental researches on malignant growths. It gives an extensive account of the excellent work done by Drs. Bashford, Murray and Cramer on transplantation of cancer in various animals and summarizes and criticizes, in the light of experimental facts, the various hypotheses concerning the nature and origin of these growths. It is significant that of all the various animals inoculated with tumors from the same species success was obtained only with the mouse. In 8,000 transplantations in mice, success varied from 1.5 to 50 per cent. In over 900 inoculations made with tumors of other animals, including dogs, rats, horses, carp, etc., not one successful result was obtained, and never were they able to transplant a tumor from one animal to any other animal of a different species, though sporadic tumors of an identical nature may be found in both species. Even in mice it was found that the percentage of successful transplantations was largely dependent on the variety of mice used. A tumor, for instance, in an English mouse inoculated into English mice of exactly the same variety would give a much higher percentage of successes than if inoculated into German mice of a slightly different variety. The same fact was noted for wild and tame mice. These facts indicate clearly the specificity of the process and are exactly comparable to the specific precipitin reactions, and perhaps even more delicate.

Attention is called to the fact that malignant growths in mice are in every way comparable to those found in human beings and behave with reference to growth, metastatic formation and other properties under artificial propagation exactly as do these growths naturally. General recognition should be given to this fact, and it should be recognized also that all the problems of cancer may be made the subject of experimental study.

In the transplanted tumors, the stroma and vascular structures introduced disintegrate and are replaced by stroma from the animal inoculated, retaining, however, the arrangement which occurred in the sporadic growth. The stroma, therefore, may be considered as a specific reaction on the part of the host and is comparable to the granulation tissue in the granulomas, being less marked only. The parenchyma, on the other hand, does not change, but goes on proliferating. If we were to carry the analogy between infections and new growths further, we might look on the tumor cells themselves as the infecting agents, comparable, for instance, to the tubercle organisms in tuberculosis, capable of indefinite proliferation when successfully transplanted and following certain definite laws of growth as any other organism does. We should look, therefore, for the explanation of the growth of tumor cells along the same lines as that of the growth of any other cell. This view is very different from the infectious hypothesis, in which it is assumed that some unknown organism is present either inside or outside the cell and stimulates its growth.

All the various hypotheses advanced to explain the origin and growth of cancer are inadequate, according to the report. Particularly do they fail in explaining the facts observed in experimental study, as most of them were advanced before it was known that cancer could be subjected to such study. The infectious theory is made the subject of particular comment, and the facts in general tend to speak against the view of cancer being an infectious disease in the sense in which the term is applied either to those diseases in which the germ is known or in those in which the organism has not yet been discovered. The apparent endemics of cancer have been explained away by properly considering the age incidence of the disease. There is absolutely no evidence derived from either animals or man that the disease is naturally communicable. The cell inclusions found in cancer have been made the subject of critical study by many pathologists, and the general trend of opinion appears to be against the view that they are specific parasites. Again, cancer is common to all vertebrates and produces identical histologic lesions in all the various species, yet the disease can not be transplanted from one species to another. This is in marked contrast to infectious diseases in man and animals. Cancer cells when transplanted continue to grow and do not degenerate as does infective granulomatous tissue when similarly transplanted. The cells arising in transplanted tumors are direct descendants of the original tumor cells and are entirely independent of the host. These are some of what appear to be vital objections to the parasitic hypothesis.

The results obtained by the application of radium emanations to tumors in mice agree with those reported by other investigators. In general there was a diminution in size after a few exposures to radium or the injection of radioactive salt solution, though this did not occur in all. Careful histologic examination revealed the fact that extensive hemorrhages occurred in the tumor thus treated, followed by connective tissue proliferation and shrinkage. They found that adrenalin in large dose produced similar hemorrhages and also led to the same favorable result. The conclusion is reached, therefore, that in these processes just mentioned, as also in instances where spontaneous healing occurs, the occurrence of hemorrhage is the preliminary condition, and the connective tissue proliferation is thus initiated.

The general result of the investigation may be summed up by stating that the explanation of the nature of cancer centers around the explanation of the power of continuous proliferation and the question of whether this growth is analyzable or not. A study of the process of growth is paramount, therefore, to all other problems, and this brings the experimental method naturally in the forefront of all other methods.

It is certainly very gratifying to read this report and to note on what broad and comprehensive lines these investigations are conducted. As a result of this study, while the nature of cancer may remain as obscure as before, yet the significance of many phases of the question certainly can be much better appreciated and one is enabled more clearly to determine the vital points of attack in the solution of this most difficult and serious problem.

PHYSICAL CONDITION OF SCHOOL CHILDREN.

Every autumn, at the beginning of the school year, it seems advisable to call attention to the fact that one of the most important features of success in school work is that the child shall be in normal health. Without this qualification it is absurd to expect the child to succeed in its studies like normal children, or even that it shall do itself justice in the trying process of the development of its faculties. If there were any need for emphasizing this point, the recent report of the Department of Health of New York with regard to the physical condition of school children in a number of metropolitan schools would furnish it amply. Altogether, 13,941 children have been examined. Of these, 6,294 were reported by the medical school inspectors as requiring medical attention. One thousand and ninety-two children were reported as poorly nourished; that is, as being in such a poor state of nutrition from lack of food as to require special care on this score. A number of the settlement workers in the slums of various American cities have recently reported that they found not a few school children in regular attendance at school who did not have breakfast before leaving home. It is, as being in such a poor state of nutrition from lack that the physicians report one out of every fourteen children as insufficiently nourished.

These figures are surely startling enough to arouse all our municipal health and educational authorities to the necessity for greater care of the physical condition of school children, but they are not all. It was found, for instance, that 3,219 children were suffering from defective vision, and that 460 children had defective hearing. Almost needless to say, children laboring from notable defects of the most important faculties used in modern educational methods, can not be expected to keep up with other children. Many of the children set down by teachers as dull were found to be suffering from either a defect of vision or of hearing, for the correction of which nothing had been done. In addition to these, 1,623 children suffered from breathing defects that frankly put them in the class of mouth-breathers. The intellectual development of the mouth-breather, as a rule, is so much retarded by this physical abnormality that it is not surprising to find that most of these children also were considered to be dull. They will continue to be backward until relieved of their serious respiratory handicap.

The examinations as made in New York seem to have been carefully carried out, and with sufficient attention to detail to make the report valuable for general statistical purposes. While the school children examined all came from the poorer districts of the city, care was taken to avoid the worst quarters, in which the mortality and morbidity rate is highest, so that the results obtained might be of average value for comparative purposes. The result, then, startling as it is, is a statement of actual conditions and not a chance statistical exaggeration. The figures we have quoted, however, point out only the educational disadvantages. There are some other details of the report of special interest to physicians. For instance, it was found that over 2,300 children were suffering from enlargements of the cervical glands. Most of these cases are doubtless tuberculous in nature. Now that we have learned how much can be accomplished by out-door air and good nutrition, in such forms of tuberculosis as enlarged glands, it seems important that these children should not be allowed to develop this disease to the extent that will make them foci of infection in the crowded neighborhoods in which they live. In other words, this careful examination of school children has given valuable material not only for the educator, but also for all those who are interested in the great work of the prevention of disease, and no more promising field for progress in the prophylaxis of disease has been opened in recent years.

THE PNEUMOCOCCUS IN HEALTH AND DISEASE.

When Sternberg, in the eighties of last century, discovered that the pneumococcus was present in the mouths of a large percentage of healthy individuals, there resulted great modifications in our conception of the pathogenesis of acute lobar pneumonia. Many had come to regard lobar pneumonia as an auto-infection, conceiving that the parasite was constantly lying in wait in the saliva of the normal individual, biding its time until undue exposure, alcoholism, or some other depressant factor had lessened the resistance sufficiently to allow it to gain a foothold in the lungs. There is little doubt that this conception, simple and attractive as it was, took too little account of other factors, especially of the factor of contagion, which the experience of large cities has tended to bring to the fore.

The first report of the Medical Commission for the Investigation of Acute Respiratory Diseases,[1] while it takes up only the bacteriologic aspects of pneumonia, brings out many points which have a bearing on the means by which the disease is transmitted. The report shows, first of all, that the broad statement that pneumococci are found in the mouths of a large percentage of healthy individuals must be modified in certain particulars. While it is probably true that a small number of people always harbor virulent pneumococci, the mass of individuals only do so from time to time. In the Eastern and Middle Western States, where the conditions of living during the winter months are distinctly modified by severe climate, it is mostly during the cold weather that a large percentage of individuals are so infected. During the spring and fall the number harboring pneumococci is very much smaller. This would seem to indicate that the altered conditions during the cold season facilitate the spread of pneumococci to a very appreciable extent. This fact accounts for the increased incidence of pneumonia during the winter months, not only because it shows increased facility for the transmission of the germ, but also because it allows of alterations in its virulence, for there is good reason to believe, on experimental grounds, that passage of the pneumococcus through human beings increases this. The report of the commission further suggests some of the means by which pneumococci are spread. They may be acquired in hospital wards, for patients in the immediate neighborhood of pneumonia cases whose saliva was originally free from pneumococci may subsequently develop them. They may be acquired under such circumstances by droplet infection, by means of dried pneumonic sputum, or by actual contact with utensils which have been used by pneumonia patients. The latter, like typhoid patients, may carry the germs of the disease for weeks or even months after recovery from the disease, and may thus remain a source of danger to others for an indefinite period. There is some evidence brought forward by the commission that others than pneumonia patients may be a source of danger, for they show that in some instances ordinary colds may, of course, transmit the germ. The prevalence of the disease in insanitary and overcrowded districts is to some extent explained by the facts above cited, and also by the further observation that in dried sputum, especially in dark places or those not exposed to direct sunlight, the pneumococci may remain alive for a month or even longer.

Apart from these facts with clinical bearing, the purely bacteriologic side of the question has been enriched by the studies made under the commission. It is shown that there is quite an important group of organisms intermediate between the pneumococci and the streptococci, and, though the clinical significance of these organisms is only beginning to be worked out, there is evidence that they are pathogenic and may be found both in pneumonia and in distant foci of inflammation, such as meningitis. The report of the commission shows that a high class of work is being accomplished under their auspices, and encourages the belief that when that work is concluded we shall be in possession of a considerable mass of new facts regarding pneumonia, and shall be in a position to understand more clearly, and combat more intelligently a disease which, in some places at any rate, is rapidly usurping the premier rôle of tuberculosis as a factor in mortality.

AMERICAN MEDICAL COLLEGES.

It is unnecessary nowadays for the American medical student to go to Europe to finish his medical education. Once it was, but not now. This is the sentiment of a short article by Dr. Nicholas Senn in the current number of *Collier's Weekly*. He calls attention to the fact that during the war of independence our surgeons carried with them text-books written by surgeons of the opposing army. Now, however, "our medical schools have gradually raised the requirements of admission, lengthened the time of college attendance, equipped laboratories, secured adequate clinical facilities, and initiated a vigorous final examination, until some of our leading schools, like the Harvard Medical School, the College of Physicians and Surgeons of New York, the University of Pennsylvania, the Johns Hopkins Medical School, and Rush Medical College, Chicago, compare well with any of the European schools. Fortunately, the elective system in teaching, so common in Europe, has found but little favor in this country. It can be safely stated that didactic teaching by lectures, recitations, demonstrations, and laboratory work is carried on in a more thorough and systematic manner in this country than anywhere else. We have hospitals for clinical teaching in our large cities which in the near future are destined to overshadow the famous clinical institutions of the Old World. Our students waste no time in beer gardens and the field of honor. They come to our medical schools with a firm determination to master the principles and practice of their chosen profession as thoroughly as possible during their pupilage, and apply themselves to the task with zeal and devotion. The numerous hospitals that are springing up in all of our large cities secure for a good percentage of our graduates appointments as internes, where they are given the best possible advantages for a successful postgraduate practical training. There is no longer any need for our students to cross the Atlantic for the purpose of studying medicine. A comparison between an equal number of recent graduates from our high-requirement medical schools and those of Europe would unquestionably result in favor of the former." All of us are decrying conditions as they relate to medical education in this country, but compared with what they have been, we ought to rejoice. There are still too many commercial schools with low entrance requirements, with mediocre teachers, with no facilities for teaching as modern medicine must be taught, and which, consequently, graduate young men and women who are totally unprepared for their life work; yet even these schools are better than they were, and—there are fewer of them. So, while matters are far from what they should be, they are better than they were—and they are getting better. Senn is right, "In less than half a century our great cities will become to the medical profession of every country what Alexandria, Athens, Bologna, Pisa, Paris, London, Edinburgh, Vienna and Berlin have been in the past and present."

IMPOSING ON PHYSICIANS' PRIVILEGES.

It is said that in Chicago the number of scorching automobiles using the red cross—which should mean that they are driven by physicians or hospital representatives—has increased so greatly of late that the police are suspicious that speed fiends are sailing under false colors. Considering that people with all sorts of moral qualifications (or lack of them) are driving automobiles, this is not impossible. Moreover, the blunting of conscience which makes so many otherwise respectable men wilfully violate the well-known ordinances as to speed, as well as the God-given rights of others, might lead to the temptation thus to evade the law. In any case, however, it is a matter that concerns physicians, and they should do all that is practicable to prevent such misrepresentation. The necessity for physicians to travel at extra speed through crowded thoroughfares does not occur often, and if in emergencies they are allowed the privilege, they should use it with due discretion. It would be a slur on the profession to say that its members can not resist the automobile mania or speed intoxication infection.

THE NEED OF PHYSICIANS AND SANITARIANS IN THE CHICAGO CHARTER CONVENTION.

Owing to its rapid growth, the city of Chicago long ago outgrew the provisions of its present charter, and at the last meeting of the legislature measures were adopted calling together a convention to draft a new, adequate charter for the city. In other words, steps have been taken to give Chicago a better form of government than it has at present, a government more in harmony with the needs of the city and with the ideals of the present day. The membership of this charter convention seems to have been determined and, unfortunately, as it now stands, there is not included therein the name of a single physician, or, so far as we can judge, of a scientifically trained sanitarian. This means that in considering the provisions in the new governmental organization for the sanitation, for the hospitals and other institutions of medical and hygienic nature of the new and improved Chicago, the charter convention must seek expert advice outside its own membership. While practically all other departments of municipal activity appear to be adequately represented in this convention, that of public health, now of such far-reaching possibilities for good if properly organized and administered, seems to have been overlooked entirely. If this be the case it certainly reflects little credit on the foresight of the public officials and bodies whose duty it was to select the members of the convention. It shows that after all there is still a lamentable ignorance in the community of the importance of public health in all its various branches. We hope some way may be found to remedy this serious defect in the charter convention as it now is composed; for without membership in the convention it becomes exceedingly difficult for medical men and expert hygienists to secure for public health the consideration it should have in the fundamental organization of the government of a city like Chicago.

THE SURGICAL TREATMENT OF TUBERCULOUS CERVICAL LYMPH GLANDS.

Although recovery from tuberculosis, wherever situated, occurs not rarely, such a result, of course, is not always to be expected. When the disease is not accessible to surgical intervention the best results will be obtained from an intelligent combination of fresh air, a generous diet and a proper adjustment of rest and exercise. On the other hand, surgical measures should be instituted when the disease is within reach. These remarks are applicable especially to tuberculosis of the lymphatic glands in the neck. Apart from the local disturbance, there is here also the danger of the conveyance of the disease to remote parts through the blood stream. Admirable results have been reported from various sources from extirpation of such tuberculous glands, the prognosis being more favorable in children than in adults. To the statistics already published may be added those recently presented by Dr. Charles N. Dowd,[1] who records the results of operation by thorough removal of the affected glands with a minimum disturbance of the surrounding tissues in 100 cases, principally in children. In his opinion, tuberculosis of the cervical lymph nodes in the large majority of cases is due apparently to infection introduced by way of the fauces, the pharynx or the nasal mucous membrane—in 86 per cent. of the cases under his own observation. Statistics show that extension to the lungs and other internal organs takes place in from one-quarter to one-half of the cases in which removal of the nodes is not undertaken. Apart from the tendency to infect other structures, the disease is tedious and a source of great discomfort and disability, and it leaves behind it disfiguring scars. Thorough removal of the diseased nodes by operation has yielded better results than any other treatment that has been thus far employed. In favorable cases the operation is entirely safe, leaving a scar that is scarcely visible. The patient will be confined to bed probably for two or three days and will be required to wear a bandage or dressing for from one and a half to three weeks. There is freedom from recurrence in about 75 per cent. and ultimate recovery in about 90 per cent. of the cases. In less favorable cases, also, the operation is safe, while the disfigurement from scars is less than that resulting from discharging sinuses. There is freedom from recurrence in from 50 to 55 per cent. and ultimate cure in from 70 to 75 per cent. of cases. The preferable incisions are transverse, either in the creases of the neck or parallel to them; they should avoid the facial nerve. A vertical incision behind the hair line is occasionally helpful. Extensive incisions are necessary in advanced cases. Every precaution should be taken to preserve the normal structures of the neck. It is not feasible to divide the cases into groups of those suitable and others unsuitable for operation. Every patient with tuberculous cervical lymph nodes should be operated on unless the operation is positively contraindicated.

A RUSSIAN NOVELIST'S VIEWS.

The distinguished Russian novelist, Maxim Gorky, whose fame has been made worldwide by his association with late events in Russia, has recently published some personal recollections of his brother novelist, Chekhov, who is also a Russian. In this work, very definite opinions with regard to the present state of the professions in Russia and apparently also in most of the rest of what these novelists are prone to think of as the over-civilized world, are pointedly expressed. Chekhov once said to Gorky, who evidently thoroughly agreed with him, "To live well, worthy of a human being, one must labor. Work, lovingly, faithfully done, is our highest privilege—with us, no one is able to do this. An architect sits down to the card table or spends his time in the wings of the theater as soon as he has succeeded in constructing two or three decent houses. A physician, as soon as he has succeeded in building up a lucrative practice for himself, loses all interest in science and never reads anything aside from the 'Notes on Therapeutics.' At forty, he is earnestly convinced that all diseases emanate from congestions and the taking of colds." This might seem rather severe on the medical profession of his native land; but his compliments to the other professions are no more favorable. "A lawyer," he says, "after he once makes a name for himself in a successfully conducted lawsuit does not trouble himself any longer with defending just causes, he takes up the defense of rich corporations, plays the races, eats oysters, and represents himself as a connoisseur in the fine arts. An actor, after rendering a few decent rôles, is likely to refuse to study further parts, dons a cylinder hat and proclaims himself a genius." At least, it is interesting to see the reflection that professional men cast in the somewhat distorted mirror of these Russian novelists' limited experience, but even from such one-sided views perhaps good may be derived, for the gift to see ourselves as others see us is too precious ever to be refused.

Medical News

ALABAMA.

Personal.—Dr. S. G. Robinson, Eufaula, is seriously ill with cerebral hemorrhage.

Bequests.—By the will of the late Dr. Joseph Riley Smith, Birmingham, Hillman Hospital and St. Vincent Hospital each received $5,000, to be paid in annual installments of $1,000 each.

Hospital Reopened.—The City Hospital at Huntsville was reopened September 8 after having been closed for several weeks for repairs. About $3,000 has been expended in remodeling and refitting the institution.

Itinerant Doctor Arrested.—"Dr." Hass, who has been selling "Shaker" medicines in Huntsville, was arrested September 9 for failure to pay license. The charge against him was dismissed when he agreed to pay the regular itinerant's license.

ARIZONA.

Board of Health for Bisbee.—The City Council of Bisbee has passed and put in force an ordinance creating a city board of health and prescribing its duties.

Personal.—Dr. H. Wilson Levengood, Mesa, is acting as U. S. G. S. surgeon at Roosevelt during the vacation of Dr. L. J. Palmer.——Dr. Allen R. Hickman of Copper Queen Hospital, Bisbee, is seriously ill at Douglas.——Dr. Charles H. Jones. Tempe, was thrown from a buggy at Mesa and sustained severe contusions.

ARKANSAS.

Sentenced to Prison.—Dr. B. H. Ward, Mount Pisgah, was found guilty at Searcy of unlawful conduct with a girl under the age of 16, and was sentenced to imprisonment for one year in the penitentiary. An appeal was asked and granted.

Personal.—Dr. Charles G. Carroll will succeed Prof. A. M. Muckenfuss as professor of chemistry in the University of Arkansas, Little Rock.——Dr. Myron E. Lane, Little Rock, has left for Europe.——Dr. William W. Jackson, Jonesboro, has resigned as a member of the State Board of Health.——Dr. and Mrs. Anderson Watkins, Little Rock, have returned from the East.——Dr. William H. Barry, president of the Federal Board, Hot Springs, who has been seriously ill, is rapidly regaining his strength.

CALIFORNIA.

Ill and Injured.—Dr. Gardner P. Pond, Fair Oaks, was thrown from his carriage in a collision September 4, had two of his ribs broken, suffered a concussion of the brain, and is in a precarious condition.——Dr. George B. Nichols, San Luis Obispo, is critically ill with cancer.

Frowns on Lodge Practice.—The Fresno County Medical Society, at its meeting September 5, adopted the following resolution regarding lodge or contract practice:

> *Resolved*, That it is the sense of this society that it is a violation of the ethics of the medical profession and against the best interests of the same, for any member of the profession to contract to do lodge or other contract practice, where the compensation is a stated sum per capita.

New Hospitals.—The Santa Fe Hospital at Los Angeles will be completed and ready to receive patients by the end of this [illegible]en finished will have cost more than [illegible] are being made for the construction of the new Clara Barton Hospital, San Francisco, which will be erected on Post Street, will accommodate eighty patients and will cost about $130,000.

Personal.—Dr. Clarence V. Thompson, radiologist at the City and County Hospital, San Francisco, has resigned.——Dr. W. Kearney, San Francisco, has been appointed volunteer medical inspector of schools.——Dr. Carroll Thrasher, San Francisco. returned from Alaska September 7.——Dr. and Mrs. John Gallwey, San Francisco, have returned from an extensive trip abroad.——Dr. James M. Steade has been appointed a member of the board of health of San Diego, vice Dr. Peter C. Remondino.——Dr. August F. Browne, Healdsburg, has given up the practice of medicine and returned to his former employment as train dispatcher for the Southern Pacific Railway in San Francisco.——Dr. Frederick W. Browning, Haywards, has returned from a trip to the East.

CONNECTICUT.

Hospital Staff Elected.—St. Vincent Hospital, Bridgeport. announces the following visiting staff: Dr. Charles C. Godfrey, surgery; Dr. Edward Fitzgerald, medicine; Dr. Henry S. Miles, ophthalmology, and Dr. Herbert E. Smyth, laryngology.

Violator of the Law.—Dr. James L. Gardner Central Village. arrested on the charge of issuing a prescription for liquor in violation of the law, pleaded guilty August 30 and was fined $20 and costs. The evidence showed that Dr. Gardner had issued twenty-one prescriptions in one month to one couple for liquor.

New Hospitals.—A site has been selected and purchased at Derby for the City Hospital, for the erection of which the late George Griffin devised the sum of $50,000.——The Cedar Mountain Hospital for tuberculosis patients, which has been closed for about two years, will reopen October 1. The state has appropriated $7,500 toward the support of the hospital and about $4,000 still remains to be raised. The hospital will accommodate, when completed, eighty-eight patients.

August Deaths.—During August, 1,419 deaths were reported to the State Board of Health. This was 241 less than in July, 47 more than in August, 1904, and 4 less than the average number of deaths for the five preceding years. The death rate for the month was equivalent to an annual mortality of 17.1 per 1,000. Among the principal causes of death were: Infantile diarrhea, 293; nervous diseases, 143; consumption, 95; heart diseases, 92; accidents and violence, 78; pneumonia, 39, and typhoid fever, 26.

Typhoid Prevalence.—An unusual prevalence of typhoid fever existed during August, 259 cases being reported, as against 173 in the corresponding month of last year. The disease is widely scattered, being reported from fifty different towns. The epidemic character of the outbreak was evidenced by the suddenness of its onset and its limited duration. ——An epidemic of typhoid has broken out among the inmates of the Springside Home, New Haven, where 13 cases have occurred. Up to the present time the source of the epidemic has not been discovered.

Personal.—Dr. W. G. Verdi, Bridgeport, has been appointed a member of the house staff of the St. Vincent Hospital.——The house of Dr. John L. Buel, Litchfield, was entered August 27 and a large amount of silverware was stolen.——Dr. Joseph Swett, Jr., New Hartford. medical examiner for New Hartford and Barkhamsted, in a collision between his buggy and a fast train at New Hartford September 12, was thrown thirty feet, but escaped without serious injury. His horse was killed.——Drs. Thomas M. Bull, William J. Delaney, Walter A. Reilly and A. E. May have been appointed inspectors of the public schools of Naugatuck.

ILLINOIS.

Diphtheria Closes Schools.—Malignant diphtheria in and around Farmington and in Green Township, Livingston County, has caused the public schools to be closed.

Subscriptions for Hospital.—It was announced at the annual conference September 19 that $20,000 has been subscribed toward the purchase of ground and for a maintenance fund for the Deaconess Hospital, Peoria.

Medical Venders Fined.—"Drs." J. B. Grubbs. L. Thomas and Charles B. Smith, charged with practicing medicine in Springfield without a license and prosecuted at the instance of the State Board of Health, were each fined $200 and costs. The defendants defaulted.

Bomb Sent Physician.—Dr. Orin C. Lamb. South Chicago, had pushed into his office, through an open door, a cigar box containing a stick of dynamite, a battery and percussion cap. Dr. Lamb considers it possible that this infernal machine was sent by a former disgruntled patient.

Sanitarium Dedicated.—The Hinsdale Sanitarium—the suburban quarters of the Lifeboat Work of Chicago—was dedicated September 20. Addresses were made by the Hon. Orrin N. Carter. Drs. James H. Kellogg. D. K. Pearsons, Homer E. Thomas, L. P. Haskell and David Paulson.

Personal.—Dr. George E. Hilgard, Bellville, captain and assistant surgeon Illinois National Guard, assigned Fifth Infantry, has resigned.——Dr. James H. Mosler, Prophetstown, injured his finger in the machinery of a windmill September 14. —Dr. and Mrs. Talbot B. Strauss, Gibson City, have gone to Denver.

County Hospital Examinations.—The members of the consulting staff of Cook County Hospital met in joint session September 19 with the Cook County Civil Service Commission to consider questions relating to the announced examination of candidates for the hospital staff. The examining board is composed as follows: Drs. Charles S. Bacon, Frank Billings, Daniel R. Brower, Heman H. Brown, Sanger Brown, Thomas J. Conley, A. C. Cowperthwaite, Nathan S. Davis, Joseph B. DeLee, Fernand Henrotin, Ferdinand C. Hotz, Stuart Johnstone, John B. Murphy, Hugh T. Patrick, Charles E. Paddock, William E. Quine, Edgar M. Reading, Nicholas Senn, George F. Shears, Horace M. Starkey, Daniel A. K. Steele, James H. Stowell, Henry S. Tucker, Charles S. Williams and Casey A. Wood. Dr. Fernand Henrotin was elected chairman of the board and Dr. Joseph B. DeLee secretary. An executive committee, which will later name the membership of the subboards for each of the twelve departments, was appointed and composed as follows: Dr. William E. Quine, chairman; Drs. John B. Murphy, Hugh T. Patrick, Joseph B. De Lee, Casey A. Wood, George F. Shears, E. M. Reading. Dr. Fernand Henrotin is a member of the committee ex-officio and Dr. De Lee was selected secretary. The executive committee will make further arrangements for the tests of candidates. Original entrance examinations must be held for the places, according to the amendment passed at the last session of the state legislature. Those who pass will be placed on the eligible list. Examinations will be held in the following branches: Surgery, medicine, nervous and mental diseases, diseases of children and contagious diseases, pathology, obstetrics, skin and venereal diseases, diseases of the eye, diseases of the ear, nose and throat, orthopedic surgery, pathologic chemistry and x-ray.

Chicago.

Personal.—Dr. and Mrs. Robert C. Wilson have returned from Europe.——Dr. Horace M. Starkey has moved to Rockford.

Banquet to Dr. Senn.—The medical profession of the city will give a banquet to Dr. Nicholas Senn Saturday, November 11. The committee of arrangements consists of Drs. William A. Evans, Frank Billings, John B. Murphy, William L. Baum and David J. Doherty.

More Smallpox.—Just after the Isolation Hospital had discharged its last smallpox patient three new cases of the disease were discovered; two of the patients were removed to the Isolation Hospital, but the third, when found, was dead from the hemorrhagic form of the disease.

Deaths of the Week.—The total deaths from all causes during the week ended September 23 numbered 512, an equivalent to an annual death rate of 13.4 per 1,000. One hundred and ninety-six of the deaths were of individuals between 20 and 60 years; 144 of infants under one year, and 82 of persons over 60. Acute intestinal diseases caused 114 deaths: consumption, 51; heart diseases, 47; violence, including suicide, 41; Bright's disease, 30; and pneumonia and nervous diseases, each 24.

INDIANA.

Dr. Brayton Returns from Yellow Fever Study.—Dr. Nelson D. Brayton has returned to Indianapolis. He has been in New Orleans for some time studying yellow fever.

Will Not Divert Hospital Fund.—At the Methodist conference in Michigan City September 16, the conference refused to divert to other channels a fund of $6,000 bequeathed to the council by Mrs. Martha Ray of Lafayette, to be used in the erection of a hospital.

Sentenced for Criminal Malpractice.—Dr. Charles L. Landfair, Bluffton, has been found guilty of having performed a criminal operation on Miss Frances Beeler and was sentenced September 18 to imprisonment in the Northern Indiana penitentiary for an indefinite period, and in addition was fined $100 and costs.

Forecast.—The State Board of Health believes that September will show a large increase in typhoid fever over August and that there will be still a larger increase in October. This prediction is made on the fact that this state of affairs prevails every year. Pneumonia and influenza deaths will begin to increase in October, or as soon as the good weather is over and people commence to live indoors.

Personal.—Dr. Joseph R. Mountain, Connersville, while driving across a railway track, collided with a freight train, but escaped in time to save his life. He was dragged a short distance, sustaining a severe sprain of the shoulder.——Dr. Madge P. Hawkins, Terre Haute, has returned from a trip through the West.——Dr. John T. Freeland, Bedford, was taken to Terre Haute September 12 for operation.——Dr. David C. Peyton, Jeffersonville, has been appointed surgeon-in-chief for the Louisville & Southern Indiana Traction Company, the United Gas and Electric Company, and the New Albany water works.——Dr. Carroll C. Cotton, Elwood, seriously injured three of his fingers by the shutting of a car door at Goldsmith September 13.——Dr. Charles L. Seitz, Evansville, has returned after two years in the Arctic regions with the Zeigler-Fiala expedition.——Dr. Albert J. Maris, Waterloo, has been appointed superintendent of a sanitarium in St. Louis.

August Disease and Death.—There was an increase in sickness and an increase in deaths in August, as compared with July, but no increase over August, 1904. Diarrhea was the most prevalent disease, and typhoid fever, which was seventh in July, arose to second place in August. There was a great deal of rheumatism, cholera morbus, cholera infantum and dysentery. Only 10 cases of smallpox were reported from five counties, and no deaths. In the corresponding month last year there were 56 cases of smallpox in 14 counties, and 3 deaths. Typhoid fever prevailed in August in every county in the state and 125 deaths occurred. Very many cases diagnosed to 55 per cent. and ultimate cure in from 70 to 75 per cent. of cases. The preferable incisions are transverse, either in the creases of the neck or parallel to them; they should avoid the facial nerve. A vertical incision behind the hair line is occasionally helpful. Extensive incisions are necessary in advanced cases. Every precaution should be taken to preserve the normal structures of the neck. It is not feasible to divide the cases into groups of those suitable and others unsuitable for operation. Every patient with tuberculous cervical lymph nodes should be operated on unless the operation is positively contraindicated.

A RUSSIAN NOVELIST'S VIEWS.

The distinguished Russian novelist, Maxim Gorky, whose fame has been made worldwide by his association with late events in Russia, has recently published some personal recollections of his brother novelist, Chekhov, who is also a Russian. In this work, very definite opinions with regard to the present state of the professions in Russia and apparently also in most of the rest of what these novelists are prone to think of as the over-civilized world, are pointedly expressed. Chekhov once said to Gorky, who evidently thoroughly agreed with him, "To live well, worthy of a human being, one must labor. Work, lovingly, faithfully done, is our highest privilege—with us, no one is able to do this. An architect sits down to the card table or spends his time in the wings of the theater as soon as he has succeeded in constructing two or three decent houses. A physician, as soon as he has succeeded in building up a lucrative practice for himself, loses all interest in science and never reads anything aside from the 'Notes on Therapeutics.' At forty, he is earnestly convinced that all diseases emanate from congestions and the taking of colds." This might seem rather severe on the medical profession of his native land; but his compliments to the other professions are no more favorable. "A lawyer," he says, "after he once makes a name for himself in a successfully conducted lawsuit does not trouble himself any longer with defending just causes, he takes up the defense of rich corporations, plays the races, eats oysters, and represents himself as a connoisseur in the fine arts. An actor, after rendering a few decent rôles, is likely to refuse to study further parts, dons a cylinder hat and proclaims himself a genius." At least, it is interesting to see the reflection that professional men cast in the somewhat distorted mirror of these Russian novelists' limited experience, but even from such one-sided views perhaps good may be derived, for the gift to see ourselves as others see us is too precious ever to be refused.

Medical News

ALABAMA.

Personal.—Dr. S. G. Robinson, Eufaula, is seriously ill with cerebral hemorrhage.

Bequests.—By the will of the late Dr. Joseph Riley Smith, Birmingham, Hillman Hospital and St. Vincent Hospital each received $5,000, to be paid in annual installments of $1,000 each.

Hospital Reopened.—The City Hospital at Huntsville was reopened September 8 after having been closed for several weeks for repairs. About $3,000 has been expended in remodeling and refitting the institution.

Itinerant Doctor Arrested.—"Dr." Hass, who has been selling "Shaker" medicines in Huntsville, was arrested September 9 for failure to pay license. The charge against him was dismissed when he agreed to pay the regular itinerant's license.

ARIZONA.

Board of Health for Bisbee.—The City Council of Bisbee has passed and put in force an ordinance creating a city board of health and prescribing its duties.

Personal.—Dr. H. Wilson Levengood, Mesa, is acting as U. S. G. S. surgeon at Roosevelt during the vacation of Dr. L. J. Palmer.——Dr. Allen R. Hickman of Copper Queen Hospital, Bisbee, is seriously ill at Douglas.——Dr. Charles H. Jones, Tempe, was thrown from a buggy at Mesa and sustained severe contusions.

ARKANSAS.

Sentenced to Prison.—Dr. B. H. Ward, Mount Pisgah, was found guilty at Searcy of unlawful conduct with a girl under the age of 16, and was sentenced to imprisonment for one year in the penitentiary. An appeal was asked and granted.

Personal.—Dr. Charles G. Carroll will succeed Prof. A. M. Muckenfuss as professor of chemistry in the University of Arkansas, Little Rock.——Dr. Myron E. Lane, Little Rock, has left for Europe.——Dr. William W. Jackson, Jonesboro, has resigned as a member of the State Board of Health.——Dr. and Mrs. Anderson Watkins, Little Rock, have returned from the East.——Dr. William H. Barry, president of the Federal Board, Hot Springs, who has been seriously ill, is rapidly regaining his strength.

CALIFORNIA.

Ill and Injured.—Dr. Gardner P. Pond, Fair Oaks, was thrown from his carriage in a collision September 4, had two of his ribs broken, suffered a concussion of the brain, and is in a precarious condition.——Dr. George B. Nichols, San Luis Obispo, is critically ill with cancer.

Frowns on Lodge Practice.—The Fresno County Medical Society, at its meeting September 5, adopted the following resolution regarding lodge or contract practice:

> *Resolved*, That it is the sense of this society that it is a violation of the ethics of the medical profession and against the best interests of the same, for any member of the profession to contract to do lodge or other contract practice, where the compensation is a stated sum per capita.

New Hospitals.—The Santa Fe Hospital at Los Angeles will be completed and ready to receive patients by the end of this month. The building when finished will have cost more than $200,000.——Preparations are being made for the construction of the new Clara Barton Hospital, San Francisco, which will be erected on Post Street, will accommodate eighty patients and will cost about $130,000.

Personal.—Dr. Clarence V. Thompson, radiologist at the City and County Hospital, San Francisco, has resigned.——Dr. W. Kearney, San Francisco, has been appointed volunteer medical inspector of schools.——Dr. Carroll Thrasher, San Francisco. returned from Alaska September 7.——Dr. and Mrs. John Gallwey, San Francisco, have returned from an extensive trip abroad.——Dr. James M. Steade has been appointed a member of the board of health of San Diego, vice Dr. Peter C. Remondino.——Dr. August F. Browne, Healdsburg, has given up the practice of medicine and returned to his former employment as train dispatcher for the Southern Pacific Railway in San Francisco.——Dr. Frederick W. Browning, Haywards, has returned from a trip to the East.

CONNECTICUT.

Hospital Staff Elected.—St. Vincent Hospital, Bridgeport, announces the following visiting staff: Dr. Charles C. Godfrey, surgery; Dr. Edward Fitzgerald, medicine; Dr. Henry S. Miles, ophthalmology, and Dr. Herbert E. Smyth, laryngology.

Violator of the Law.—Dr. James L. Gardner Central Village. arrested on the charge of issuing a prescription for liquor in violation of the law, pleaded guilty August 30 and was fined $20 and costs. The evidence showed that Dr. Gardner had issued twenty-one prescriptions in one month to one couple for liquor.

New Hospitals.—A site has been selected and purchased at Derby for the City Hospital, for the erection of which the late George Griffin devised the sum of $50,000.——The Cedar Mountain Hospital for tuberculosis patients, which has been closed for about two years, will reopen October 1. The state has appropriated $7,500 toward the support of the hospital and about $4,000 still remains to be raised. The hospital will accommodate, when completed, eighty-eight patients.

August Deaths.—During August, 1,419 deaths were reported to the State Board of Health. This was 241 less than in July, 47 more than in August, 1904, and 4 less than the average number of deaths for the five preceding years. The death rate for the month was equivalent to an annual mortality of 17.1 per 1,000. Among the principal causes of death were: Infantile diarrhea, 293; nervous diseases, 143; consumption, 95; heart diseases, 92; accidents and violence, 78; pneumonia, 39, and typhoid fever, 26.

Typhoid Prevalence.—An unusual prevalence of typhoid fever existed during August, 259 cases being reported, as against 173 in the corresponding month of last year. The disease is widely scattered, being reported from fifty different towns. The epidemic character of the outbreak was evidenced by the suddenness of its onset and its limited duration. ——An epidemic of typhoid has broken out among the inmates of the Springside Home, New Haven, where 13 cases have occurred. Up to the present time the source of the epidemic has not been discovered.

Personal.—Dr. W. G. Verdi, Bridgeport, has been appointed a member of the house staff of the St. Vincent Hospital.——The house of Dr. John L. Buel, Litchfield, was entered August 27 and a large amount of silverware was stolen.——Dr. Joseph Swett, Jr., New Hartford, medical examiner for New Hartford and Barkhamsted, in a collision between his buggy and a fast train at New Hartford September 12, was thrown thirty feet, but escaped without serious injury. His horse was killed.——Drs. Thomas M. Bull, William J. Delaney, Walter A. Reilly and A. E. May have been appointed inspectors of the public schools of Naugatuck.

ILLINOIS.

Diphtheria Closes Schools.—Malignant diphtheria in and around Farmington and in Green Township, Livingston County, has caused the public schools to be closed.

Subscriptions for Hospital.—It was announced at the annual conference September 19 that $20,000 has been subscribed toward the purchase of ground and for a maintenance fund for the Deaconess Hospital, Peoria.

Medical Venders Fined.—"Drs." J. B. Grubbs, L. Thomas and Charles B. Smith, charged with practicing medicine in Springfield without a license and prosecuted at the instance of the State Board of Health, were each fined $200 and costs. The defendants defaulted.

Bomb Sent Physician.—Dr. Orin C. Lamb, South Chicago, had pushed into his office, through an open door, a cigar box containing a stick of dynamite, a battery and percussion cap. Dr. Lamb considers it possible that this infernal machine was sent by a former disgruntled patient.

Sanitarium Dedicated.—The Hinsdale Sanitarium—the suburban quarters of the Lifeboat Work of Chicago—was dedicated September 20. Addresses were made by the Hon. Orrin N. Carter, Drs. James H. Kellogg, D. K. Pearsons, Homer E. Thomas, L. P. Haskell and David Paulson.

Personal.—Dr. George E. Hilgard, Bellville, captain and assistant surgeon Illinois National Guard, assigned Fifth Infantry, has resigned.——Dr. James H. Mosler, Prophetstown, injured his finger in the machinery of a windmill September 14. —Dr. and Mrs. Talbot B. Strauss, Gibson City, have gone to Denver.

County Hospital Examinations.—The members of the consulting staff of Cook County Hospital met in joint session September 19 with the Cook County Civil Service Commission to consider questions relating to the announced examination of candidates for the hospital staff. The examining board is composed as follows: Drs. Charles S. Bacon, Frank Billings, Daniel R. Brower, Heman H. Brown, Sanger Brown, Thomas J. Conley, A. C. Cowperthwaite, Nathan S. Davis, Joseph B. DeLee, Fernand Henrotin, Ferdinand C. Hotz, Stuart Johnstone, John B. Murphy, Hugh T. Patrick, Charles E. Paddock, William E. Quine, Edgar M. Reading, Nicholas Senn, George F. Shears, Horace M. Starkey, Daniel A. K. Steele, James H. Stowell, Henry S. Tucker, Charles S. Williams and Casey A. Wood. Dr. Fernand Henrotin was elected chairman of the board and Dr. Joseph B. DeLee secretary. An executive committee, which will later name the membership of the subboards for each of the twelve departments, was appointed and composed as follows: Dr. William E. Quine, chairman; Drs. John B. Murphy, Hugh T. Patrick, Joseph B. De Lee, Casey A. Wood, George F. Shears, E. M. Reading. Dr. Fernand Henrotin is a member of the committee ex-officio and Dr. De Lee was selected secretary. The executive committee will make further arrangements for the tests of candidates. Original entrance examinations must be held for the places, according to the amendment passed at the last session of the state legislature. Those who pass will be placed on the eligible list. Examinations will be held in the following branches: Surgery, medicine, nervous and mental diseases, diseases of children and contagious diseases, pathology, obstetrics, skin and venereal diseases, diseases of the eye, diseases of the ear, nose and throat, orthopedic surgery, pathologic chemistry and x-ray.

Chicago.

Personal.—Dr. and Mrs. Robert C. Wilson have returned from Europe.——Dr. Horace M. Starkey has moved to Rockford.

Banquet to Dr. Senn.—The medical profession of the city will give a banquet to Dr. Nicholas Senn Saturday, November 11. The committee of arrangements consists of Drs. William A. Evans, Frank Billings, John B. Murphy, William L. Baum and David J. Doherty.

More Smallpox.—Just after the Isolation Hospital had discharged its last smallpox patient three new cases of the disease were discovered; two of the patients were removed to the Isolation Hospital, but the third, when found, was dead from the hemorrhagic form of the disease.

Deaths of the Week.—The total deaths from all causes during the week ended September 23 numbered 512, an equivalent to an annual death rate of 13.4 per 1,000. One hundred and ninety-six of the deaths were of individuals between 20 and 60 years; 144 of infants under one year, and 82 of persons over 60. Acute intestinal diseases caused 114 deaths; consumption, 51; heart diseases, 47; violence, including suicide, 41; Bright's disease, 30; and pneumonia and nervous diseases, each 24.

INDIANA.

Dr. Brayton Returns from Yellow Fever Study.—Dr. Nelson D. Brayton has returned to Indianapolis. He has been in New Orleans for some time studying yellow fever.

Will Not Divert Hospital Fund.—At the Methodist conference in Michigan City September 16, the conference refused to divert to other channels a fund of $6,000 bequeathed to the council by Mrs. Martha Ray of Lafayette, to be used in the erection of a hospital.

Sentenced for Criminal Malpractice.—Dr. Charles L. Landfair, Bluffton, has been found guilty of having performed a criminal operation on Miss Frances Beeler and was sentenced September 18 to imprisonment in the Northern Indiana penitentiary for an indefinite period, and in addition was fined $100 and costs.

Forecast.—The State Board of Health believes that September will show a large increase in typhoid fever over August and that there will be still a larger increase in October. This prediction is made on the fact that this state of affairs prevails every year. Pneumonia and influenza deaths will begin to increase in October, or as soon as the good weather is over and people commence to live indoors.

Personal.—Dr. Joseph R. Mountain, Connersville, while driving across a railway track, collided with a freight train, but escaped in time to save his life. He was dragged a short distance, sustaining a severe sprain of the shoulder.——Dr. Madge P. Hawkins, Terre Haute, has returned from a trip through the West.——Dr. John T. Freeland, Bedford, was taken to Terre Haute September 12 for operation.——Dr. David C. Peyton, Jeffersonville, has been appointed surgeon-in-chief for the Louisville & Southern Indiana Traction Company, the United Gas and Electric Company, and the New Albany water works.——Dr. Carroll C. Cotton, Elwood, seriously injured three of his fingers by the shutting of a car door at Goldsmith September 13.——Dr. Charles L. Seitz, Evansville, has returned after two years in the Arctic regions with the Zeigler-Fiala expedition.——Dr. Albert J. Maris, Waterloo, has been appointed superintendent of a sanitarium in St. Louis.

August Disease and Death.—There was an increase in sickness and an increase in deaths in August, as compared with July, but no increase over August, 1904. Diarrhea was the most prevalent disease, and typhoid fever, which was seventh in July, arose to second place in August. There was a great deal of rheumatism, cholera morbus, cholera infantum and dysentery. Only 10 cases of smallpox were reported from five counties, and no deaths. In the corresponding month last year there were 56 cases of smallpox in 14 counties, and 3 deaths. Typhoid fever prevailed in August in every county in the state and 125 deaths occurred. Very many cases diagnosed "malaria," "chills," "debility," "slight fever," are found to be typhoid by microscopical tests. The deaths numbered 3,070, equivalent to an annual rate of 13.6 per 1,000. In the corresponding month of last year there were 2,980 deaths. By important ages the deaths were: 665 under 1 year of age; 287, 1 to 5; 53, 5 to 10; 55, 10 to 15; 90, 15 to 20; 735, 65 and over. Tuberculosis caused 340 deaths; diphtheria, 12; scarlet fever, 6; whooping cough, 15; pneumonia, 61; diarrheal diseases, 478; cerebrospinal meningitis, 56; influenza, 1; puerperal fever, 8; cancer, 126, and violence, 190. Of the deaths by violence 7 were homicides, 34 were suicides and the remainder accidental, of whom 27 were drowned, 11 shot and 5 killed by horses.

IOWA.

New Hospital Opened.—The new City Hospital at Shenandoah was formally opened September 10.

College Opens.—The Keokuk Medical College of Physicians and Surgeons was formally opened for the year's work September 12. The address of the evening was delivered by Dr. Frank P. Norbury, Jacksonville, Ill., who sketched the history of medicine as shown in the lives of great physicians.

Personal.—Dr. James Taggart Priestley, Des Moines, has returned from a trip to Japan.——Dr. Albert P. Johnson, Sigourney, was seriously injured in a railroad wreck near Rock Island, Ill., September 4.——Dr. B. L. Sheldon, Cedar Rapids, sails September 30 for Vienna.——Dr. James F. Batten, Onawa, has been appointed coroner of Monona County.

Itinerant Practitioners.—Judge Cosewell, Marshalltown, has ruled that the traveling medicine men, calling themselves "Phenomenal Kraus" and "The Great Anselme," charged with practicing medicine without a license, must furnish a bond of $600 on each of four indictments. The defendants claim that they not only have itinerant licenses, but that the diagnosticians in their employ are physicians du[illegible] A warrant has been sworn out by Dr. A. C. [illegible] the local member of the State Board of Health, against the "Minnesota Boy Healer" on the ground that he is engaged in the irregular practice of medicine.——"Brother Paul," an itinerant medicine man, who suddenly left Freeport, Ill., under indictment on fourteen charges, has as suddenly left Burlington, as he was threatened with prosecution by the State Board of Medical Examiners.——The "Great Paul," alias J. Ferdon, was arrested at Fort Madison for practicing without a license, complaint being made by Dr. Carl W. Wahrer, local health officer. He is now in jail. This is the same individual who was mentioned in The Journal of September 9.

KENTUCKY.

Pest House Empty.—The St. John's Eruptive Hospital. Louisville, has been without an occupant for two months.

Diphtheria.—About 50 cases of diphtheria are reported in Franklin County and the public school at Grassy Springs has been closed on account of the disease.

Personal.—Dr. Joseph M. Ferguson, second assistant physician at the Western Kentucky Hospital for the Insane, Hopkinsville, is seriously ill with appendicitis.——Dr. and Mrs. James B. Bullitt and family, Louisville, have returned after a two months' visit to California.——Dr. William A. Briggs, Bowling Green, who has been seriously ill with typhoid fever, has recovered.

Low Death Rate.—The annual report of the health officer of Louisville shows that the death rate for the last fiscal year was 16.79 per 1,000. The chief causes of death were: Tuberculosis, 541; pneumonia, 363; heart diseases, 305; inanition, 207; cancer, 133; nephritis, 160; enterocolitis, 115; typhoid fever, 113; apoplexy, 148; meningitis, 117; paralysis, 105, and bronchitis, 112.

Diphtheria Prevalent.—On account of the prevalence of diphtheria in Franklin County the street fair which was to have been held this month has been postponed. Dr. Arthur T. McCormack, secretary of the State Board of Health, went to Frankfort on September 15 to consult with the local health officers regarding the diphtheria situation. There are said to be 300 cases of the disease in the county.

MARYLAND.

Meeting of Faculty.—About 75 physicians attended the semi-annual meeting of the Medical and Chirurgical Faculty of Maryland, held at Deer Park, last week.

New Quarantine Boat.—The board of estimates has appropriated $15,000 for the purchase of a new boat for the quarantine station, as the old one leaked badly. Dr. Sidney P. Heiskell, quarantine officer, has the offer of a wooden boat from New York, and the board agreed to the purchase of that and made an additional appropriation of $2,000 for necessary alterations.

Personal.—Dr. Lewellys F. Barker arrived at Baltimore September 22 after a summer on Go Home Bay, Canada.——Dr. William Whitridge, Baltimore, is at Lucerne, Switzerland.——Dr. William H. Smith, formerly resident physician at the Hebrew Hospital, Baltimore, is in Vienna.——Dr. and Mrs. Benjamin Rush Ridgely, Warren, Baltimore County, celebrated their golden wedding anniversary September 20.

NEBRASKA.

Personal.—Dr. Julius P. Sedgwick and wife and daughter have returned from Berlin.——Dr. John K. Maxson, formerly of Lincoln, has been committed to the insane asylum. He is said to be suffering from paresis resulting from the use of drugs and liquor.——Dr. R. G. Rich, David City, pursued a burglar out of his house, seized him and, in spite of receiving severe wounds, held him until help arrived. Dr. Rich is expected to recover.——Dr. J. L. Greene, Lincoln, superintendent of the state insane institution, has resigned as examining physician of the county insane commission.——Dr. E. J. C. Sward, Oakland, has been made a member of the State Board of Health.

NEW YORK.

New York City.

Held at Quarantine.—Four of the passengers of the steamship *Comus*, arrived from New Orleans on September 18, were sent to Hoffman's Island for observation.

Bequest for Hospital.—The will of the late Ferdinand Meyer sets apart a certain portion of his estate, of which the exact amount is not yet known, for charitable purposes. Mount Sinai Hospital is to receive one-quarter of this amount.

Purification of Water Supply.—The board of estimate has taken steps toward purifying the water supply by holding public hearings on the proposition to acquire certain lands at Mount Kisco, which are regarded as a menace to the water channels in that district. They anticipate purchasing 113,234 acres of land having an assessed value of $70,000.

Contagious Diseases.—There were reported to the sanitary bureau for the week ended September 16, 444 cases of tuberculosis, with 136 deaths; 172 cases of diphtheria, with 23 deaths; 132 cases of typhoid fever, with 22 deaths; 72 cases of measles, with 2 deaths; 38 cases of scarlet fever, with 4 deaths; 8 cases of cerebrospinal meningitis, with 15 deaths, and 15 cases of varicella.

Going and Coming.—Dr. Samuel G. Tracy returned on the *Philadelphia* September 16.——Dr. and Mrs. John G. Curtis and Dr. and Mrs. William S. Dennett returned on the *Prinzessen Irene* September 20.——Dr. Arthur C. Brush, Brooklyn, returned on the *Cretic* September 17.——Drs. Gordon R. Hall and J. A. McCorkle returned on the *United States* September 17.——Dr. George R. Lockwood returned on the *Frederick der Grosse* September 21.——Dr. and Mrs. D. B. Hardenburgh sailed on the *Prinzessen Irene* September 23.

Model Tenements.—Plans for the first of the model tenement houses to be built with money from the $1,000,000 gift by Henry Phipps are on file. The main features include careful sanitation, fountains in the interior courtyards, roof gardens, kindergartens and the newest appliances for housework. The first of these buildings will be put up in East Thirty-fifth Street between First and Second Avenues. This site was selected because of the cosmopolitan population. There will be from two to four rooms in each suite and the rooms will all be open to the air. The rent will not exceed $15 a month for any apartment.

OHIO.

Arrested, Fined, Flees.—"Dr." Andrew Robinson, a member of a patent medicine show at Niles, who was fined $25 and costs for criminal assault September 11, fled from the town before paying his fine.

New Hospital.—The Ruth Hospital at the Children's Home, Hamilton, was formally d[illegible] 16.——The cornerstone of the new Good [illegible] Zanesville, was laid with due ceremonies September 24.

Accept Annuity Proposition.—At a meeting of the trustees of the Painesville Hospital they accepted the proposition made by Mrs. J. L. Whetstone to give the hospital $1,000 on the condition that an 8 per cent. annuity be paid her.

Colleges Opened.—The Medical Department of the Toledo University opened September 28. Dr. Park L. Myers has been appointed dean of the department, succeeding Dr. William A. Dickey.——Starling Medical College, Columbus, opened September 13 for its fifty-sixth annual session. Dr. Starling Loving, dean of the college, gave a clinical lecture as the opening address, and this marked the beginning of the forty-eighth year of Dr. Loving's connection with the faculty of the college.

The Afflicted.—Dr. Martin L. Williams, Warren is critically ill with pneumonia.——Dr. Lewis D. Brumm, Celina, fell while alighting from a car in St. Mary's and fractured his clavicle. ——Dr. William E. Wheatley, Lorain, was operated on for appendicitis September 12 at the Lakeside Hospital, Cleveland, and is reported to be doing well.——Dr. Albert L. King, Youngstown, is critically ill.——Dr. Collins M. Hoover, Alliance, fell downstairs a few days ago and sprained his ankle. ——Dr. Jerome Bland, Bucyrus, had a cerebral hemorrhage August 31 and is in a precarious condition.

Personal.—Dr. Alexander M. Steinfeldt, Columbus, left for Europe September 2.——Dr. Mary L. Austin has been appointed assistant physician at the Ohio Hospital for Epileptics, Gallipolis, and Dr. Rose E. Timmons has been appointed assistant physician at the Toledo State Hospital.——Dr. Arthur E. Evans has resigned as surgeon of the Baltimore & Ohio Railroad in Columbus and Dr. William L. Dick has been appointed in his stead.——Dr. J. C. Sheets and Dr. Daniel W. Gans, Massillon, have returned from a trip to the Pacific Coast.——Dr. Myron Metzenbaum, Cleveland, has been awarded the bronze medal for "Original Research in Chemistry, Physics and the Medical Value of Radium," by the jury of awards of the Louisiana Purchase Exposition, St. Louis.

PENNSYLVANIA.

Smallpox.—It is reported that there are at least 30 fully developed cases of smallpox near Williamsburg. As usual, the cases were at first diagnosed as chickenpox.

Injured.—Dr. John H. Enterline, Shamokin, was thrown from his sulky in a runaway accident. His left knee was badly wrenched and he sustained severe contusions.

Fined for Not Reporting Contagious Case.—For neglecting to report cases of diphtheria to the Board of Health, Dr. Milton H. Weaver, Richlandtown, was arrested September 11 and fined $10 and costs.

Personal.—Dr. and Mrs. Thomas H. Gray, Erie, have returned from an extended trip to the Northwest.——Dr. and Mrs. James K. Pollock and family, New Castle, returned September 9 after a trip to the Pacific Coast.

Sells Practice: Resumes It: Court Enjoins.—Judge Johnson granted an injunction September 23 on petition of Dr. Howard F. Taylor of Ridley Park, restraining Dr. David McMasters from practicing in the borough or interfering with the practice of Dr. Taylor. Dr. McMasters sold his practice to Dr. Taylor in April, 1904, for $300, and promised to refrain from practice in Ridley Park.

Philadelphia.

Personal.—Drs. T. Oram Ring, James A. Kearney and Boardman Reed have returned from Europe.——Dr. William H. Temple has been seriously ill in the Medico-Chirurgical Hospital.

Carnival Cash for Charity.—The sum of $1,100 was realized from the street carnival held in behalf of the St. Agnes and the Methodist hospitals. The proceeds are to be divided equally.

Fined for Speeding Autos.—Drs. John B. Deaver, Philadelphia, and Henry Stoeber, Chester, were arrested in Philadelphia September 8, charged with speeding their automobiles. Each was fined $12.62, which was promptly paid.

Hospital Reports for August.—St. Agnes' Hospital admitted 180 patients to the wards and treated 625 new and 1,972 old cases in the dispensaries.——There were 152 patients admitted to the wards of St. Mary's Hospital and 580 new and 1,508 old cases were treated in the clinics.

Bacteriologic Laboratory Report.—The report of the bacteriologic laboratory of the Health Bureau reveals that 805 diphtheria examinations were made, 424 specimens of blood, 1,058 specimens of milk and 100 specimens of sputum were examined, and that 853 bottles of antitoxin were distributed.

Impure Food Indictments.—Forty persons were indicted by the grand jury September 22 for alleged violation of the pure food laws. The specific offenses were: Adulterated soda syrups, 21; adulterated jams and preserves, 5; adulterated chocolate cake, 3; oleomargarin, 3; adulterated ginger, 1; adulterated meats, 3.

Medical Business and Ethics.—At a stated meeting of the Philadelphia County Medical Society, held June 21, a resolution was adopted conveying a request that each medical school furnish its senior class with a special course of lectures or addresses on the subjects of medical ethics and the business aspect of the practice of medicine, and including the recommendation that graduates promptly join the local county medical society.

Jewish Charities Report.—The Federation of the Jewish Charities for the fiscal year ended April 30 reports that $118,600 was distributed during the year to 12 charitable institutions. Among these the Jewish Hospital Association received $30,000; the Jewish Foster Home, $20,000; the United Hebrew Charities, $28,200; the Jewish Maternity Association, $8,000; the Jewish Emigration Society, $800, and the National Jewish Home for Consumptives, $3,000.

To Suppress Bogus Hospitals.—As a result of investigations made by United States Postal Inspector Malone, an effort will be made to suppress the practice of bogus doctors and medical concerns of various kinds in the city. An appeal will also be made to the Board of Health to revoke the licenses of a number of lying-in establishments, on the ground that they are being used for criminal malpractice. Letters in the possession of the inspector will be used as evidence against the proprietors of these so-called hospitals in which offers are made to perform operations at prices ranging from $5 to $500.

Health Report.—The deaths reported from all causes for last week numbered 409. This is an increase of 20 over those reported the previous week and an increase of 8 over those reported the corresponding period of last year. The principal causes of death were as follows:. Typhoid fever, 11; consumption, 50; cancer, 16; apoplexy, 24; heart disease, 33; acute respiratory disease, 22; enteritis, under 2 years, 39; enteritis, over 2 years, 17; Bright's disease, 28; accidents, 13; marasmus, 16. There were 184 cases of contagious disease reported, with 13 deaths, as compared with 166 cases and 16 deaths for the previous week.

Will Have Bulletin.—The medical societies of Philadelphia commenced the publication of a weekly bulletin, similar to that issued for the last three years by the Chicago Medical Society. It contains the programs of the affiliated societies, announcements of meetings, and items of interest to the local profession. Dr. A. B. Hirsch, 1711 Diamond Street, is the editor. In the issue for September 16, the information blank for the Biographical Card Index and American Medical Directory is copied, with the request that each physician fill out and return the blank in order to insure full registration of the Philadelphia profession.

GENERAL.

Excursion to International Medical Congress.—Arrangements have been completed for chartering a vessel on which the American delegates to the Fifteenth International Medical Congress at Lisbon, April 19-26, may sail as one party. The organization of the party is in the hands of the following committee: Drs. Lewis S. McMurtry, Louisville; Nicholas Senn, Chicago; J. B. Griffith, Kansas City, Mo.; W. F. Southard, San Francisco; Frank P. Norbury, Jacksonville, Ill.; W. T. Corlett, Cleveland, Ohio; C. H. Hughes, St. Louis, Mo.; R. T. Morris, New York City; A. Vander Veer, Albany, N. Y.; Joseph M. Mathews, Louisville; J. B. Murphy, Chicago; F. B. Turck, Chicago; James E. Moore, Minneapolis; Charles Wood Fassett (secretary in charge), St. Joseph, Mo. The party will sail from New York April 7 on the North German Lloyd steamer *König Albert;* some will return May 9 and others later or by a different route. Itineraries of various tours are being prepared. Further information regarding reservations and copies of itinerary may be obtained by addressing Dr. Charles Wood Fassett, Krug Park Place, St. Joseph, Mo. Those wishing to become members of or contribute to the congress, should communicate with the secretary of the American committee, Dr. Ramon Guiteras, 75 W. Fifty-fifth street, New York City.

The Journal of Biological Chemistry.—Announcement is made of a new journal by this name, to be edited by Drs. C. A. Herter, New York, and J. J. Abel, Baltimore. The scope of the journal will be appreciated from the following taken from the announcement just received:

> Without rigidly defining the scope of the journal, it may be stated that its pages will be open
>
> 1. To workers in zoölogy and botany and the branches of knowledge in which these sciences are applied, for such of their researches as are of a chemical or physico-chemical nature.
> 2. To workers on the chemical side of the experimental medical sciences, as physiology, pathology, pharmacology, hygiene, physiologic chemistry and bacteriology.
> 3. To those who are engaged in any branch of clinical medicine, when their researches are of a chemical nature.

"malaria," "chills," "debility," "slight fever," are found to be typhoid by microscopical tests. The deaths numbered 3,070, equivalent to an annual rate of 13.6 per 1,000. In the corresponding month of last year there were 2,980 deaths. By important ages the deaths were: 665 under 1 year of age; 287, 1 to 5; 53, 5 to 10; 55, 10 to 15; 90, 15 to 20; 735, 65 and over. Tuberculosis caused 340 deaths; diphtheria, 12; scarlet fever, 6; whooping cough, 15; pneumonia, 61; diarrheal diseases, 478; cerebrospinal meningitis, 56; influenza, 1; puerperal fever, 8; cancer, 126, and violence, 190. Of the deaths by violence 7 were homicides, 34 were suicides and the remainder accidental, of whom 27 were drowned, 11 shot and 5 killed by horses.

IOWA.

New Hospital Opened.—The new *City Hospital at Shenandoah* was formally opened September 10.

College Opens.—The Keokuk Medical College of Physicians and Surgeons was formally opened for the year's work September 12. The address of the evening was delivered by Dr. Frank P. Norbury, Jacksonville, Ill., who sketched the history of medicine as shown in the lives of great physicians.

Personal.—Dr. James Taggart Priestley, Des Moines, has returned from a trip to Japan.——Dr. Albert P. Johnson, Sigourney, was seriously injured in a railroad wreck near Rock Island, Ill., September 4.——Dr. B. L. Sheldon, Cedar Rapids, sails September 30 for Vienna.——Dr. James F. Batten, Onawa, has been appointed coroner of Monona County.

Itinerant Practitioners.—Judge Cesewell, Marshalltown, has ruled that the traveling medicine men, calling themselves "Phenomenal Kraus" and "The Great Anselme," charged with practicing medicine without a license, must furnish a bond of $600 on each of four indictments. The defendants claim that they not only have itinerant licenses, but that the diagnosticians in their employ are physicians duly registered.——A warrant has been sworn out by Dr. A. C. Moerke, Burlington, the local member of the State Board of Health, against the "Minnesota Boy Healer" on the ground that he is engaged in the irregular practice of medicine.——"Brother Paul," an itinerant medicine man, who suddenly left Freeport, Ill., under indictment on fourteen charges, has as suddenly left Burlington, as he was threatened with prosecution by the State Board of Medical Examiners.——The "Great Paul," alias J. Ferdon, was arrested at Fort Madison for practicing without a license, complaint being made by Dr. Carl W. Wahrer, local health officer. He is now in jail. This is the same individual who was mentioned in The Journal of September 9.

KENTUCKY.

Pest House Empty.—The St. John's Eruptive Hospital. Louisville, has been without an occupant for two months.

Diphtheria.—About 50 cases of diphtheria are reported in Franklin County and the public school at Grassy Springs has been closed on account of the disease.

Personal.—Dr. Jose [illegible] second assistant physician at the Western [illegible] for the Insane, Hopkinsville, is seriously ill with appendicitis.——Dr. and Mrs. James B. Bullitt and family, Louisville, have returned after a two months' visit to California.——Dr. William A. Briggs, Bowling Green, who has been seriously ill with typhoid fever, has recovered.

Low Death Rate.—The annual report of the health officer of Louisville shows that the death rate for the last fiscal year was 16.79 per 1,000. The chief causes of death were: Tuberculosis, 541; pneumonia, 363; heart diseases, 305; inanition, 207; cancer, 133; nephritis, 160; enterocolitis, 115; typhoid fever, 113; apoplexy, 148; meningitis, 117; paralysis, 105, and bronchitis, 112.

Diphtheria Prevalent.—On account of the prevalence of diphtheria in Franklin County the street fair which was to have been held this month has been postponed. Dr. Arthur T. McCormack, secretary of the State Board of Health, went to Frankfort on September 15 to consult with the local health officers regarding the diphtheria situation. There are said to be 300 cases of the disease in the county.

MARYLAND.

Meeting of Faculty.—About 75 physicians attended the semi-annual meeting of the Medical and Chirurgical Faculty of Maryland, held at Deer Park, last week.

New Quarantine Boat.—The board of estimates has appropriated $15,000 for the purchase of a new boat for the quarantine station, as the old one leaked badly. Dr. Sidney P. Heiskell, quarantine officer, has the offer of a wooden boat from New York, and the board agreed to the purchase of that and made an additional appropriation of $2,000 for necessary alterations.

Personal.—Dr. Lewellys F. Barker arrived at Baltimore September 22 after a summer on Go Home Bay, Canada.——Dr. William Whitridge, Baltimore, is at Lucerne, Switzerland.——Dr. William H. Smith, formerly resident physician at the Hebrew Hospital, Baltimore, is in Vienna.——Dr. and Mrs. Benjamin Rush Ridgely, Warren, Baltimore County, celebrated their golden wedding anniversary September 20.

NEBRASKA.

Personal.—Dr. Julius P. Sedgwick and wife and daughter have returned from Berlin.——Dr. John K. Maxson, formerly of Lincoln, has been committed to the insane asylum. He is said to be suffering from paresis resulting from the use of drugs and liquor.——Dr. R. G. Rich, David City, pursued a burglar out of his house, seized him and, in spite of receiving severe wounds, held him until help arrived. Dr. Rich is expected to recover.——Dr. J. L. Greene, Lincoln, superintendent of the state insane institution, has resigned as examining physician of the county insane commission.——Dr. E. J. C. Sward, Oakland, has been made a member of the State Board of Health.

NEW YORK.

New York City.

Held at Quarantine.—Four of the passengers of the steamship *Comus*, arrived from New Orleans on September 18, were sent to Hoffman's Island for observation.

Bequest for Hospital.—The will of the late Ferdinand Meyer sets apart a certain portion of his estate, of which the exact amount is not yet known, for charitable purposes. Mount Sinai Hospital is to receive one-quarter of this amount.

Purification of Water Supply.—The board of estimate has taken steps toward purifying the water supply by holding public hearings on the proposition to acquire certain lands at Mount Kisco, which are regarded as a menace to the water channels in that district. They anticipate purchasing 113,234 acres of land having an assessed value of $70,000.

Contagious Diseases.—There were reported to the sanitary bureau for the week ended September 16, 444 cases of tuberculosis, with 136 deaths; 172 cases of diphtheria, with 23 deaths; 132 cases of typhoid fever, with 22 deaths; 72 cases of measles, with 2 deaths; 38 cases of scarlet fever, with 4 deaths; 8 cases of cerebrospinal meningitis, with 15 deaths, and 15 cases of varicella.

Going and Coming.—Dr. Samuel G. Tracy returned on the *Philadelphia* September 16.——Dr. and Mrs. John G. Curtis and Dr. and Mrs. William S. Dennett returned on the *Prinzessen Irene* September 20.——Dr. Arthur C. Brush, Brooklyn, returned on the *Cretic* September 17.——Drs. Gordon R. Hall and J. A. McCorkle returned on the *United States* September 17.——Dr. George R. Lockwood returned on the *Frederick der Grosse* September 21.——Dr. and Mrs. D. B. Hardenburgh sailed on the *Prinzessen Irene* September 23.

Model Tenements.—Plans for the first of the model tenement houses to be built with money from the $1,000,000 gift by Henry Phipps are on file. The main features include careful sanitation, fountains in the interior courtyards, roof gardens, kindergartens and the newest appliances for housework. The first of these buildings will be put up in East Thirty-fifth Street between First and Second Avenues. This site was selected because of the cosmopolitan population. There will be from two to four rooms in each suite and the rooms will all be open to the air. The rent will not exceed $15 a month for any apartment.

OHIO.

Arrested, Fined, Flees.—"Dr." Andrew Robinson, a member of a patent medicine show at Niles, who was fined $25 and costs for criminal assault September 11, fled from the town before paying his fine.

New Hospital.—The Ruth Hospital at the Children's Home, Hamilton, was formally dedicated September 16.——The cornerstone of the new Good Samaritan Hospital, Zanesville, was laid with due ceremonies September 24.

Accept Annuity Proposition.—At a meeting of the trustees of the Painesville Hospital they accepted the proposition made by Mrs. J. L. Whetstone to give the hospital $1,000 on the condition that an 8 per cent. annuity be paid her.

Colleges Opened.—The Medical Department of the Toledo University opened September 28. Dr. Park L. Myers has been appointed dean of the department, succeeding Dr. William A. Dickey.——Starling Medical College, Columbus, opened September 13 for its fifty-sixth annual session. Dr. Starling Loving, dean of the college, gave a clinical lecture as the opening address, and this marked the beginning of the forty-eighth year of Dr. Loving's connection with the faculty of the college.

The Afflicted.—Dr. Martin L. Williams, Warren is critically ill with pneumonia.——Dr. Lewis D. Brumm, Celina, fell while alighting from a car in St. Mary's and fractured his clavicle.——Dr. William E. Wheatley, Lorain, was operated on for appendicitis September 12 at the Lakeside Hospital, Cleveland, and is reported to be doing well.——Dr. Albert L. King, Youngstown, is critically ill.——Dr. Collins M. Hoover, Alliance, fell downstairs a few days ago and sprained his ankle.——Dr. Jerome Bland, Bucyrus, had a cerebral hemorrhage August 31 and is in a precarious condition.

Personal.—Dr. Alexander M. Steinfeldt, Columbus, left for Europe September 2.——Dr. Mary L. Austin has been appointed assistant physician at the Ohio Hospital for Epileptics, Gallipolis, and Dr. Rose E. Timmons has been appointed assistant physician at the Toledo State Hospital.——Dr. Arthur E. Evans has resigned as surgeon of the Baltimore & Ohio Railroad in Columbus and Dr. William L. Dick has been appointed in his stead.——Dr. J. C. Sheets and Dr. Daniel W. Gans, Massillon, have returned from a trip to the Pacific Coast.——Dr. Myron Metzenbaum, Cleveland, has been awarded the bronze medal for "Original Research in Chemistry, Physics and the Medical Value of Radium," by the jury of awards of the Louisiana Purchase Exposition, St. Louis.

PENNSYLVANIA.

Smallpox.—It is reported that there are at least 30 fully developed cases of smallpox near Williamsburg. As usual, the cases were at first diagnosed as chickenpox.

Injured.—Dr. John H. Enterline, Shamokin, was thrown from his sulky in a runaway accident. His left knee was badly wrenched and he sustained severe contusions.

Fined for Not Reporting Contagious Case.—For neglecting to report cases of diphtheria to the Board of Health, Dr. Milton H. Weaver, Richlandtown, was arrested September 11 and fined $10 and costs.

Personal.—Dr. and Mrs. Thomas H. Gray, Erie, have returned from an extended trip to the Northwest.——Dr. and Mrs. James K. Pollock and family, New Castle, returned September 9 after a trip to the Pacific Coast.

Sells Practice: Resumes It: Court Enjoins.—Judge Johnson granted an injunction September 23 on petition of Dr. Howard F. Taylor of Ridley Park, restraining Dr. David McMasters from practicing in the borough or interfering with the practice of Dr. Taylor. Dr. McMasters sold his practice to Dr. Taylor in April, 1904, for $300, and promised to refrain from practice in Ridley Park.

Philadelphia.

Personal.—Drs. T. Oram Ring, James A. Kearney and Boardman Reed have returned from Europe.——Dr. William H. Temple has been seriously ill in the Medico-Chirurgical Hospital.

Carnival Cash for Charity.—The sum of $1,100 was realized from the street carnival held in behalf of the St. Agnes and the Methodist hospitals. The proceeds are to be divided equally.

Fined for Speeding Autos.—Drs. John B. Deaver, Philadelphia, and Henry Stoeber, Chester, were arrested in Philadelphia September 8, charged with speeding their automobiles. Each was fined $12.62, which was promptly paid.

Hospital Reports for August.—St. Agnes' Hospital admitted 180 patients to the wards and treated 625 new and 1,972 old cases in the dispensaries.——There were 152 patients admitted to the wards of St. Mary's Hospital and 580 new and 1,508 old cases were treated in the clinics.

Bacteriologic Laboratory Report.—The report of the bacteriologic laboratory of the Health Bureau reveals that 805 diphtheria examinations were made, 424 specimens of blood, 1,058 specimens of milk and 100 specimens of sputum were examined, and that 853 bottles of antitoxin were distributed.

Impure Food Indictments.—Forty persons were indicted by the grand jury September 22 for alleged violation of the pure food laws. The specific offenses were: Adulterated soda syrups, 21; adulterated jams and preserves, 5; adulterated chocolate cake, 3; oleomargarin, 3; adulterated ginger, 1; adulterated meats, 3.

Medical Business and Ethics.—At a stated meeting of the Philadelphia County Medical Society, held June 21, a resolution was adopted conveying a request that each medical school furnish its senior class with a special course of lectures or addresses on the subjects of medical ethics and the business aspect of the practice of medicine, and including the recommendation that graduates promptly join the local county medical society.

Jewish Charities Report.—The Federation of the Jewish Charities for the fiscal year ended April 30 reports that $118,600 was distributed during the year to 12 charitable institutions. Among these the Jewish Hospital Association received $30,000; the Jewish Foster Home, $20,000; the United Hebrew Charities, $28,200; the Jewish Maternity Association, $8,000; the Jewish Emigration Society, $800, and the National Jewish Home for Consumptives, $3,000.

To Suppress Bogus Hospitals.—As a result of investigations made by United States Postal Inspector Malone, an effort will be made to suppress the practice of bogus doctors and medical concerns of various kinds in the city. An appeal will also be made to the Board of Health to revoke the licenses of a number of lying-in establishments, on the ground that they are being used for criminal malpractice. Letters in the possession of the inspector will be used as evidence against the proprietors of these so-called hospitals in which offers are made to perform operations at prices ranging from $5 to $500.

Health Report.—The deaths reported from all causes for last week numbered 409. This is an increase of 20 over those reported the previous week and an increase of 8 over those reported the corresponding period of last year. The principal causes of death were as follows: Typhoid fever, 11; consumption, 50; cancer, 16; apoplexy, 24; heart disease, 33; acute respiratory disease, 22; enteritis, under 2 years, 39; enteritis, over 2 years, 17; Bright's disease, 28; accidents, 13; marasmus, 16. There were 184 cases of contagious disease reported, with 13 deaths, as compared with 166 cases and 16 deaths for the previous week.

Will Have Bulletin.—The medical societies of Philadelphia commenced the publication of a weekly bulletin, similar to that issued for the last three years by the Chicago Medical Society. It contains the programs of the affiliated societies, announcements of meetings, and items of interest to the local profession. Dr. A. B. Hirsch, 1711 Diamond Street, is the editor. In the issue for September 16, the information blank for the Biographical Card Index and American Medical Directory is copied, with the request that each physician fill out and return the blank in order to insure full registration of the Philadelphia profession.

GENERAL.

Excursion to International Medical Congress.—Arrangements have been completed for chartering a vessel on which the American delegates to the Fifteenth International Medical Congress at Lisbon, April 19-26, may sail as one party. The organization of the party is in the hands of the following committee: Drs. Lewis S. McMurtry, Louisville; Nicholas Senn, Chicago; J. B. Griffith, Kansas City, Mo.; W. F. Southard, San Francisco; Frank P. Norbury, Jacksonville, Ill.; W. T. Corlett, Cleveland, Ohio; C. H. Hughes, St. Louis, Mo.; R. T. Morris, New York City; A. Vander Veer, Albany, N. Y.; Joseph M. Mathews, Louisville; J. B. Murphy, Chicago; F. B. Turck, Chicago; James E. Moore, Minneapolis; Charles Wood Fassett (secretary in charge), St. Joseph, Mo. The party will sail from New York April 7 on the North German Lloyd steamer *König Albert;* some will return May 9 and others later or by a different route. Itineraries of various tours are being prepared. Further information regarding reservations and copies of itinerary may be obtained by addressing Dr. Charles Wood Fassett, Krug Park Place, St. Joseph, Mo. Those wishing to become members of or contribute to the congress, should communicate with the secretary of the American committee, Dr. Ramon Guiteras, 75 W. Fifty-fifth street, New York City.

The Journal of Biological Chemistry.—Announcement is made of a new journal by this name, to be edited by Drs. C. A. Herter, New York, and J. J. Abel, Baltimore. The scope of the journal will be appreciated from the following taken from the announcement just received:

> Without rigidly defining the scope of the journal, it may be stated that its pages will be open
>
> 1. To workers in zoölogy and botany and the branches of knowledge in which these sciences are applied, for such of their researches as are of a chemical or physico-chemical nature.
>
> 2. To workers on the chemical side of the experimental medical sciences, as physiology, pathology, pharmacology, hygiene, physiologic chemistry and bacteriology.
>
> 3. To those who are engaged in any branch of clinical medicine, when their researches are of a chemical nature.

4. To the specialist in organic chemistry, who will find here a fitting place for the publication of researches which have biologic or medical interest.

The growing importance of chemical research in the elucidation of general biologic and medical problems, and also the increasing activity of American investigators in this field, point to the need of a journal of the character here outlined. At present there is no periodical in the English language that meets the requirements of the biologic chemist.

With the hearty co-operation of American investigators the editors feel confident that the new journal will prove truly representative of the best work in biologic chemistry.

We have no doubt that the journal will receive the co-operation of the scientific men of America, as it undoubtedly will deserve such co-operation. Its price will be $3 a volume. Communications for the journal should be addressed to 810 Madison Avenue, New York.

Yellow Fever News.—In New Orleans the epidemic is gradually wearing itself out. The daily number of new cases averages about 35, and deaths about four or five. At the infected points in Louisiana the disease still spreads, although there is great improvement at the worst points. At Tallulah Dr. J. H. Anderson has the fever, as has also Dr. C. M. Shanley of Jefferson, both having been actively engaged in sanitary work.—— At Algiers a lawyer sued for trespass Surgeon Currie, Marine-Hospital Service, and his assistants for fumigating his house. He lost his case and was in turn prosecuted for failure to obey the mosquito ordinance. At some points the friction between medical men over the diagnosis of yellow fever is extreme.—— In Mississippi there has been some spread of the infection to new points, but in general the situation is fully under control. Vicksburg and Natchez each have had about 50 cases and five deaths. The coast is nearly free of new cases.——In Florida the epidemic at Pensacola still continues to be menacing, over 50 cases having occurred there.——In Georgia the quarantine contest between the state and city boards of health has got into court. Dr. J. J. Knott of Atlanta has tried to persuade the United States Public Health and Marine-Hospital Service that yellow fever is phosphorous poisoning caused by phosphoric exhalations from swamps and that turpentine is the real prophylactic.——Cincinnati has five cases of yellow fever at the contagious disease branch of the City Hospital. The patients were refugees from Tallulah and Lake Providence, La. Detroit threatened Cincinnati with quarantine.——Delegates from twelve states will meet at Chattanooga on November 9 and 10 to discuss quarantine and related matters.——Yellow fever will be discussed at the second international sanitary convention to be held at Washington, beginning October 9.——Dr. Goldberger and Dr. Rosenau of the United States Public Health and Marine-Hospital Service are now on detail at New Orleans to study the bacteriology of yellow fever.——Lexington, Ky., has two refugees ill with yellow fever.——The New Orleans record to September 26 is: New cases Septembr 25, 37; total cases, 2,868; deaths September 25, 3; total deaths, 370; death rate, 12.9 per cent.

CANADA.

New Convalescent Home for Winnipeg.—Winnipeg hospitals being generally overcrowded, it is proposed to erect a convalescent home, where patients as soon as they have become convalescent, will be removed, to make room for new patients in the hospitals.

McGill Medical Faculty Reopens.—On September 19 the opening lecture of the medical faculty of McGill University was delivered by Dr. A. Jacobi of New York. Dr. Jacobi dealt chiefly with reminiscences on medical education. The most important statement and the one which pleased the student body was: "I dislike the name of 'specialist.'"

Toronto's Good Health.—One year ago there were 21 cases of scarlet fever in Toronto. This year there has not been a single case reported since July 29. Up to September 15 there were reported 22 cases of diphtheria. A year ago there were 86 cases in the whole of September; in August there were 48 cases. There were 19 cases of typhoid fever in September last year; already there have been that number up to September 15. Last month there were 38 cases.

Change in Railway Medical Fees.—The system in vogue as regards the treatment of employes of the Canadian Northern Railway by medical men has been changed. Formerly 50 cents a month was deducted on all salaries under $100 a month, and $1 on all salaries over. This was handed by the railway to the physicians who were to supply treatment, medicines and hospital attendance. This for some time has not been satisfactory to the employés and they have organized an association, appointed a leading Winnipeg physician as chief of their medical staff, and will hereafter conduct their own sick benefit matters.

Winnipeg General Hospital.—The following figures show the increase in the work of the Winnipeg General Hospital during the month of August, 1905, over that of August, 1904 The number of patients treated in August, 1905, was 613; in August, 1904, 512; the number of days' treatment in August, 1905, 7,394; in August, 1904, 5,771; number of patients treated from Jan. 1 to Aug. 31, 1905, 2,904; in 1904, 2,412; number of outpatients treated in August, 1905, 395; in August, 1904, 292; number of deaths in August, 1905, 28; in August, 1904, 25. The total number of individuals treated during the week ending September 16 was 329, of whom 207 were men, 92 women and 40 children.

Personal.—Dr. Park and Dr. James Anderson of Hamilton, Ont., have gone to England.——Dr. Jacobi of New York will deliver the opening lecture to the Medical Faculty of McGill University at the opening of the coming session.——Dr. A. S. Monro, Vancouver, B. C., has gone to the hospitals of England for several months.——Dr. George H. Matthewson, Montreal, has gone to Naples and Vienna.——Dr. J. M. Eaton of Carberry, Man., accompanied by Dr. Schaffner of Boissevain, Man., has gone to represent Manitoba at the American Public Health Convention at Boston.——Dr. W. A. Clark has resigned his position as resident physician of St. Boniface Hospital, Winnipeg, and will practice in Arcola, Man. He has been succeeded by Dr. R. N. Burns.

Dr. R. A. Reeve, President British Medical Association.—On September 19 two medical meetings of some importance took place in Toronto. The first was a general meeting of the profession of Toronto, and the second a meeting of the local branch of the British Medical Association. The former was presided over by Dr. A. J. Johnson, and the particular item of business transacted was the appointment of a special committee to confer with the local branch in regard to the arrangements for the meeting here in August, 1906. At the meeting of the local branch Dr. R. A. Reeve, dean of the medical faculty of Toronto University, was unanimously elected to the office of president. Chairmen and secretaries have been appointed for twelve sections. The committee of arrangements has not yet been chosen.

Convention Re the Insane in Ontario.—A conference has been called by the minister of the crown in Ontario, under whose jurisdiction is the administration of the asylums and hospitals of the province, the object being to discuss the care and general management of the insane. The medical superintendents and other officers will meet the minister on September 20, and among the subjects discussed will be the limit which should be placed on the admittance of those afflicted with senile decay, the regulations that should govern the admission of defectives and degenerates, and the conditions under which an insane person should be committed to jail. Another matter to be investigated will be that of payment for people confined therein at the public expense, which ought to be borne by friends of such individuals.

Personals and News Items.—The Guelph Sanitarium is building an addition to cost $100,000.——The medical faculty of Laval University, Montreal, opened for the session on September 15. Dr. E. P. Lachapelle delivered the opening address.——Dr. W. H. Montague, formerly of Hamilton, Ont., has removed to Winnipeg, but will not practice medicine.—— Dr. W. J. Bell, surgeon, R. M. S. *Empress of India*, Vancouver, has resigned and has returned to Toronto.——Dr. Allan H. Adams, superintendent of the Toronto Free Hospital for Consumptives, has resigned and has been appointed a house surgeon in the Toronto General Hospital.——Dr. J. W. Good, Winnipeg, has donated a complete operating room to St. Boniface Hospital, Winnipeg.——The force of the Canada army medical corps will hereafter consist of 150, all ranks, of whom 9 will be stationed at London, 10 at Toronto, 11 at Kingston, 9 at Montreal, 9 at Fredericton, 20 at Halifax and 10 at Winnipeg. The remainder will be located in the west at places not yet selected.

Toronto General Hospital.—The outdoor departments of the Toronto General Hospital have undergone alterations and improvements during the summer, the total cost of which has been borne by one of the trustees, Mr. Cawthra Mulock. The board of trustees are at once to embark on a vigorous campaign to raise funds for the new hospital, which, it is expected, will be completed for occupation in three years. There is the possibility of the appointment of a new board of management. In such case the present hospital trust will be able to hand over to them the property of the existing trust valued at $600,000, producing annually nearly $25,000. The Ontario government has voted $250,000 and has authorized the University of Toronto to grant an additional $50,000. The city of Toronto has granted $200,000 and Mr. Cawthra Mulock has given $100,000, and there is said to be available from another private source an additional $100,000, which with the subscriptions to be asked from wealthy citizens will enable the trustees to make a good start toward what promises to be one of the finest hospitals in America.

Ontario Alienists Confer.—A conference of the medical superintendents of the various provincial hospitals of Ontario for the insane took place in Toronto on September 20, the object being to confer with the minister under whose department these institutions are governed. Dr. W. N. Barnhardt, Toronto, read a paper advocating pathologic work in these institutions. Dr. D. Campbell Meyers, Toronto, contributed a paper on the prevention of insanity, and advocated wards in general hospitals for functional nervous cases, too often confined to the hospitals for the insane. This met with pronounced favor, and it is likely the government will move in the matter at an early day. The chairman of the Toronto General Hospital Trust was present and stated that his hospital was prepared to adopt this principle at once and had set apart the residence of the former superintendent, Dr. Charles O'Reilly, for that purpose. Another matter dealt with was the question of insane people being jailed. Resolutions were passed favoring instructing magistrates not to commit such people unless application for their admittance had been made to some of the provincial hospitals. Hereafter the medical superintendents will not be required to do any clerical work, such as the making of reports, to the department of the government.

FOREIGN.

Yellow Fever in Brazil.—During the week ending August 13 there were three deaths from yellow fever in Rio de Janeiro, and seven new cases were reported, of which number six were verified.

Date of British Medical Association.—At the meeting of the Toronto branch of the British Medical Association, September 19, it was decided that August 21-24, 1906, should be the date of the next meeting of the British Medical Association, to be held in Toronto, Canada.

Plague in India.—According to *Public Health Reports*, the cholera epidemic in Madras is steadily increasing, the total number of deaths from the middle of July to the middle of August being about 1,000. On August 14 there was an outbreak in the Church of Scotland Zenana Mission; 15 cases and 7 deaths were reported.

Yellow Fever in Guatemala.—Consul-General Ow[illegible] reports that yellow fever has spread from the coast into [illegible] The towns of Zacapa and Gualan, on the line of the Guatemala Northern Railway, are infected. Deaths from yellow fever are also reported to have occurred at Tucura, at the head of the Polochi Valley.

Variola in Chili.—There is very little new information regarding the outbreak of variola in Chili. It is stated that the epidemic in Valparaiso has undergone considerable amelioration. Statistics from the various cities are conflicting, however. It is stated that the number of deaths from this cause in Valparaiso from January 1 to August 24 is 3,560, showing that the epidemic has been a very serious one.

Cholera in China.—Acting Assistant Surgeon Ransom of the Public Health and Marine-Hospital Service reports from Shanghai that cholera is absent from the official statistics, but that he has definite knowledge of the death of one person, a foreigner, from this disease, and that an Englishman died suddenly under suspicious circumstances. Dr. Ransom states that cholera is reported to be very prevalent in the city of Hanku.

Typhoid Fever in France.—It is reported that there is an epidemic of typhoid fever in the department of the Seine-et-Oise. The epidemic began at Pontoise and extended toward Gagny. It is attributed to the dispersal of sewage water over the fields in this district where the soil is principally limestone. Through fissures in the soil, wells are contaminated by seepage. Active measures have been instituted to restrict the spread of the disease.

Correction Concerning Quarantine at Inagua.—Dr. W. T. Williams, medical health officer of Inagua, British West Indies, desires to correct a Pennsylvania news item in The Journal of August 12, which states that the steamship *Barnston* from Colon "put into Inagua for medical attendance on account of sickness of two of her crew, who were put off at that place.' Dr. Williams states that the *Barnston* put into Inagua with 15 of her crew sick, but as he was not certain in regard to the diagnosis, the cases looking suspiciously like yellow fever, no communication was allowed with the shore, with the exception that two men were sent aboard to assist in working the ship to its destination. As there is no hospital at Inagua no accommodation could have been made for the men had they been brought ashore.

New Treatment of Cholera.—Prof. J. Stumpf of Würzburg has been testing in the prevailing cholera epidemic in Germany a means of treating the disease which he thinks will arrest and abort it and any other infectious gastrointestinal affection. The aim is to change the environment for the bacteria so that they are unable to propagate and they die off. This he accomplishes by burying them under a layer of Fuller's earth. He gives from 70 to 100 gm. of Fuller's earth, stirred into a pint of water, having the patient sip it all within twenty to thirty minutes. He gives 30 gm. to children, and 10 to 15 gm. to infants. No food should be taken for eighteen to twenty-four hours and no alcohol. Even in advanced stages its action has proved beneficial, and it has proved very successful in all forms of gastrointestinal infections in his experience. His preliminary communication on the subject is published in the *Berliner klin. Wochft.* of September 11.

Recent Public Health Regulations in Germany.—The Hamburg courts recently prohibited the public advertising of "corpulin" as a remedy for obesity, claiming that it conflicted with the decree in regard to medicines, dated June 1, 1900. The courts also imposed a penalty for delivering morphin on a forged prescription. The Berlin courts have further prohibited the sale of hydrochloric acid without a prescription to a person not known to the dealer to be reliable. The Trier court recently decided that the advertising of a method of curing deafness, worded in such a way as not to deceive the public, can not be forbidden by police authority. The Prussian courts have prohibited the public announcements in regard to the so-called remedy "oxydonor-victory," claiming that it comes under the ban of goods offered for sale with intent to deceive. The text of the above proceedings is published in the Transactions of the Imperial Council of Health.

Medical Substituting.—The Prussian Medical Court of Honor recently fined a physician $125 and costs, with some other penalties, for failing to provide a substitute when he left his practice for a few weeks. The suit was brought at the instance of a patient whom he had been treating for a leg ulcer. The physician left unexpectedly and instructed his servant to tell any patient calling for him to apply to some other physician. This patient did not call in another physician for several weeks, when the condition of the lesion was found to have become so much worse from lack of care that amputation was necessary. The Court of Honor affirmed that it was his professional duty to inform—by letter at least—this patient, whom he had been treating for nineteen weeks, that he was going away, and to impress on him the necessity to have the treatment continued by some other physician. The court held it incumbent on a physician, in case of his absence from town, to see that some one will do his work in so far that the continuance of appropriate treatment of patients in his charge shall be ensured.

Cholera in Europe.—The Journal of September 2 quoted the *St. Petersb. Med. Wochft.* of August 4 to the effect that it had been officially announced that no case of cholera had been known to occur in Russia since April. "The suspicious cases had proved to be some other disease on microscopic examination." Our German and French exchanges also published this announcement, but they are now calling Russia to task for what must evidently have been a misrepresentation of facts and breach of the international sanitary agreement, if the inner circles of the government were not better informed than the general public anouncement. If this proves not to have been the case, the chancellor of the realm is urged to take steps to protect Germany against further violations by Russia of the international sanitary agreement and the dangers resulting therefrom. Cable advices September 26 state that the total of cases in Germany to date has been 246, with 85 deaths. Two new cases and two deaths were reported in the preceding twenty-four hours, all in eastern Prussia. One patient was found September 23 in Berlin, a canal boatman from the infected district in the *northeast.* His boat was moored in the river in the heart of Berlin; all the bathing houses along the *river* have been closed and other measures taken. There have been several cases in Galicia, and the Austrian authorities have redoubled their vigilance.

Pellagra in Italy.—The Italian government has been successful in reducing the prevalence of pellagra in that country, as proved by the recently published statistics. In a period of 22 years the number of those afflicted with this disease fell from 104,000 in 1881 to 72,000 in 1899, and to 60,000 in 1902. In Latium, which till recently was immune, several cases were reported, but the further spread of the disease was checked by the energetic measures adopted by the provincial pellagra commission. Of these measures the most efficacious and essential is the active surveillance exercised on the importation and sale of maize, which is the food mainly used by the poorer classes of the rural population. Corn which has been pronounced unfit for human food may be used for animals and for the distillation of spirits, but it must first be "denaturized." This may be accomplished in various ways, care being taken that the change in appearance thus produced is a permanent one which will render the unwholesome flour or grain easily recognizable. When this is to be used as food for animals, molasses or refuse from cheese or jam factories or a quantity of oil residue mixed with the pods of legumes is added to it and the whole is then seasoned with rock salt. To determine whether a sample of maize is fit for human food the examiner notes that it has the natural lustrous appearance and the characteristic sweetish odor and taste of the sound grain. If the surface is moldy or the taste acrid or bitter the corn is condemned. While part of the specimen may come up to the required standard and be sufficiently mature, well dried and in good preservation, it is necessary to see that not more than 5 per cent. of the grains are damaged. To decide this chemical tests are also employed. When, on combustion, the quantity of ash exceeds 4 per cent., and when extracts from the maize give, with ferric chlorid, an evident phenolic reaction (indicating the development of mycetes), the grain is rejected. Other tests of good maize are that at least 80 per cent. of the grains should possess germinating power and that extracts made from it and injected into animals should not produce toxic effects. By such means and by energetic and vigilant control over the importation of maize into the country and over its supply to the population who use it for alimentary purposes much is being done to preserve the poor in the rural districts of Italy from the ravages of a terrible disease.

LONDON LETTER.

The Health of London.

The report of the Metropolitan Asylums Board for 1904, which has just been issued, contains much interesting information with regard to the health of London in that year. The board now possesses 17 infectious hospitals, 5 asylums for imbeciles, a training-ship, 15 homes or schools for certain classes of children, and 8 ambulance stations. During the year 21,183 patients passed through the fever hospitals and 538 through the smallpox hospitals. Special attention is called to the decline in the mortality from diphtheria, which in 1893, the year before the introduction of the antitoxin treatment, was as high as 30.4 per cent. At one of the hospitals a record has been kept of the mortality rates according to the day of the disease on which the antitoxin treatment was commenced. Of 204 cases treated during the years 1897 to 1904, on the first day of the disease not a single one was fatal; of 1,278 treated on the second day the mortality was 5.4 per cent.; whereas, in cases not treated until the fifth day or later, the rate has been upward of 22 per cent. The cases of mistaken diagnosis numbered no fewer than 1,993, a percentage on the total admissions of 10.7. These cases were detained in hospital an average of twenty-five days. In the board's imbecile asylums 8,026 persons have been under care; 5,853 have passed through the various children's homes and schools.

The Neglect of Vaccination: 20,000 Warrants to Serve in Derby.

The anti-vaccination cranks muster in great strength in certain towns of England. In such towns the municipal authorities, who are elected by the people, are strongly antivaccinationist and, consequently, do not enforce the law. Of these Leicester has been the most notorious, but it seems that Derby has eclipsed it. An extraordinary position has arisen as the result of twenty years' official neglect to enforce the vaccination act. It is estimated that there are no fewer than 20,000 defaulters against whom distress warrants have been issued but not executed. Representations have from time to time been made to the government with a view to enforcing the law. The home secretary has now sent an ultimatum which has caused some consternation. He has informed the watch committee that unless the police take steps to execute the warrants he will withdraw the government grant toward the aid of the police, which last year amounted to $30,000. Accordingly the town council instructed the chief constable to put the act into operation. But apart from the formidable nature of the task the anti-vaccinationist feeling is so strong that none of the local auctioneers will conduct the sale of the property of defaulters.

Outbreak of Ice-Cream Poisoning in Birmingham.

Dr. J. Robertson, health officer of Birmingham, has presented a report on a remarkable outbreak of 52 cases of ice-cream poisoning in that city. The interval from taking the ice-cream to the onset of symptoms varied from half an hour to eight and one-half hours. All the patients complained of pain in the stomach and vomiting. In the majority of cases there were diarrhea and collapse. Chemical analysis showed none of the ordinary poisons in the ice-cream. Bacteriologic examination showed that it contained a poison capable of causing inflammation and death in guinea-pigs. This was due to the presence of a bacillus or bacilli of the colon group. About 250 persons purchased the ice-cream, which was made amid very insanitary surroundings and in close proximity to three water closets in a filthy state. Professor Leith, who made the bacteriologic examination, conjectures that excremental organisms were blown into one of the buckets of ice-cream while it was in a warm condition and that rapid multiplication of the organisms took place.

Report of the Commission on Sleeping Sickness of the Royal Society.

The continuation report on sleeping sickness in Uganda by Captain Greig, I.M.S., and Lieutenant Gray, R.A.M.C., has just been published. The evidence brought forward shows: 1, That sleeping sickness is at first a specific polyadenitis caused by the *Trypanosome gambiense;* 2, that a constant lymphocytosis exists at all stages of the disease; 3, that sleeping sickness is the last stage of this disease and is invariably fatal; 4, that resistance of both men and monkeys varies greatly and that acquired immunity is probable; 5, that the action of arsenic *in vita* on the *Trypanosome gambiense* is partial; 6, that bacterial invasion, chiefly coccal, occurs in some cases in the very last days of the sleeping sickness stage of the disease and, therefore, can not determine the onset of this phase of the malady; 7, that in Uganda trypanosomes other than the *T. gambiense* are pathogenic in animals; 8, that these differ entirely from *T. gambiense;* 9, that one of these is probably identical with *T. brucci;* 10, that all trypanosomes are conveyed from the sick to the healthy by the tsetse fly, *Glossina palpalis,* and not by other biting flies (*stomoxys*). In the sleeping sickness areas of Uganda from 50 to 75 per cent. of the inhabitants are in the stage of polyadenitis and are carrying on their ordinary work. These infected people, as they present no symptoms of illness, are especially liable to infect "clean" fly belts and so spread the disease. Recently the districts around Lake Albert and the source of the Nile have become infected and the presence or absence of *Glossina palpalis* in Egypt becomes an important factor in determining the spread of the disease to the north along the shores of the Nile. A newly discovered feature in the morbid anatomy of sleeping sickness is a curious condition of the stomach, comparable with the petechial hemorrhages found under the endocardium and epicardium in trypanosoma infections. The lymphatic glands in every case of sleeping sickness are enlarged and the juice taken by puncture during life contains active trypanosomes.

Irrational Treatment of the Severely Injured.

In a letter to the *Lancet* Mr. C. H. Whiteford makes a very vigorous protest against the current practice of ordering the immediate removal to hospital of a person who has been severely crushed or mangled. The result is the inquest at which the house surgeon reports that the patient was in a state of collapse from which he never rallied and that he died a few hours later. The necropsy often shows an injury which was not incompatible with survival. To remove a patient in a state of collapse, often in a jolting uncovered vehicle over a long distance, is the most certain method of diminishing or destroying any chance of recovery. While it is unadvisable to leave a severely injured man in a gutter or open field, his removal to the nearest place of shelter, usually only a distance of a few yards, is all that is necessary. Here, under the influence of stimulants and warmth, he will recover from the shock, if such recovery is compatible with his injuries. Later he may be removed to a hospital. With the possible exception of cases of internal hemorrhage or injury to internal organs—conditions frequently combined or indistinguishable—the immediate treatment of a severely injured patient can nearly always be summarized as arrest of hemorrhage, rest at or near the scene of the accident, warmth, stimulants, saline injection and, if pain is marked, hypodermic injection of morphin.

A variant of the newspaper account of the inquest is as follows: "The house surgeon stated that the deceased was admitted in a state of collapse, the crushed limbs were at once amputated, but the patient never rallied and died in the evening." Very few severely injured patients survive the extra shock produced by immediate removal to the hospital, followed at once by operation under anesthetic. The fact of a limb being crushed beyond hope of recovery does not justify its immediate removal. The retention for some hours, or even a day, of a mangled limb will not kill the patient, but its removal plus the administration of an anesthetic while he is in a state of collapse is apt to be the "last straw." The immediate treatment of a patient who is brought collapsed to hospital should, as a rule be limited to combating the collapse, immediate operation being reserved for such cases as those of internal hemorrhage still going on, in which operation is urgently required.

Fighting Yellow Fever.

At the request of the colonial office the Liverpool School of Tropical Medicine, with the consent of the university authorities, has requested Professor Boyce to visit Belize, in British Honduras, to report on the sanitary measures in that colony necessary in view of the recent outbreak of yellow fever. Professor Boyce, who is now at New Orleans, after completing his observations of the methods employed by the Americans in combating yellow fever, will then proceed to Belize. The latest advices from Brazil have brought news that both members of the yellow fever expedition of the Liverpool school at Manaos have been ill with yellow fever, one very seriously. The expedition expresses the hope that they will now be immune.

Correspondence

The Anti-Tuberculosis Work in Missouri.

St. Louis, Sept. 18, 1905.

To the Editor:—The best way to fight tuberculosis is to fight it; the best agency in the fight is education. During the past year Missouri has made a great advance in the warfare against consumption, and the work has been taken up earnestly and intelligently both by the physicians and the laity. Two lines of action have been followed—one, the organization of local associations for the study and prevention of tuberculosis; the other, the providing for private and public sanatoria, which in themselves are object-lessons teaching the great principles of limitation.

At the last meeting of the state association, a resolution was passed asking each county society to appoint a committee on local organization, and this is to be acted on throughout the state this winter. In the larger towns action is already being taken in the formation of societies and the appointing of committees on legislation and education.

In St. Louis the Society for the Prevention of Tuberculosis has not been idle. Over 250,000 leaflets and cards have been distributed, placards have been placed in street cars and factories, and literature of different kinds bearing on the subject has been distributed by the school children. The daily press and weekly periodicals have given much space to the presentation of facts, and this has been one of the greatest helps. Lectures have been given in many places by members of the society and many more are scheduled for the winter.

The antispitting law came into effect some time ago, and its observance will be more urgently demanded as a police regulation. The new law providing for the registration of consumptives and the disinfection of apartments occupied by them is one of the best ordinances ever passed in St. Louis. It was framed to be as elastic as possible, and yet in its essential points it is effective.

A most important factor in the educational work is the sanatorium, and Missouri is well advanced in this respect. It is not to be expected that any institution can care for a large percentage of the consumptives in the adjacent territory, but it can reach them all through its influence. The state has this year given $50,000 with which to begin the building and maintaining of a sanatorium for tubercular patients. The board of commissioners intrusted with the duty of locating and building the sanatorium have visited the more prominent institutions in the country and with much care have selected a site at Mount Vernon, in the southwestern part of the state. In addition to this being a most charming and healthful locality, the citizens gave a site of 165 acres, valued at $8,500, with $7,000 in cash, free telephone service and free water and electric light for five years. Of course, while this is a most encouraging beginning, it is only a beginning, but there is no doubt that if this money is judiciously expended the state will amply provide for such additions as may be needed in the future. The commission expects to make the educational feature a large part of the work, and in this to enlist the influence of every reputable physician not only to aid in further legislation, but in giving his personal help in molding public opinion and instructing in the necessary methods for prevention. The commissioners are making large plans, and there is little doubt of success if the work so far accomplished is a criterion.

The private sanatoria in the state are meeting with success. Several of more or less pretention have been started during the past year and several "tent cities" are being planned. Mount St. Rose Sanatorium, in St. Louis, has had over 600 cases in less than three years, and, although the new building was thought large enough, it is now in mind to double the capacity. In the new City Hospital a special building is designated for the consumptives, and the Board of Health is doing all possible to enforce every ordinance and provide for every demand originating in the needs of this work.

But neither the public nor the private institutions, nor both together, can care for all of the 5,000 cases of tuberculosis estimated to exist in St. Louis. Possibly they can not care for 10 per cent., and yet they can be of more value as teachers than as care-takers. At some of these institutions every visiting friend of the patients is given a small leaflet of "instructions" regarding the methods of communication of the disease, prevention, etc., and these are the people most interested. It is following what Dr. Trudeau says: "Give the tubercular patients (and friends) education by means of a pamphlet so that they may learn not to infect others and to care for themselves."

William Porter.

Marriages

John B. Ury, M.D., to Miss Lura Kuhn, both of Defiance, Ohio, September 20.

Jacob Prinzing, M.D., to Miss Leah Florence Bourk, both of Ontario, Ore., September 14.

Oliver Fisher, M.D., Sloan, Iowa, to Miss Mina Norwood of Denver, Colo., September 3.

Southgate Leigh, M.D., to Miss Alice Creekmore, both of Norfolk, Va., September 20.

M. D. Baker, M.D., to Miss Mary Reede Riley, both of Waco, Texas, September 27.

Frederick R. Greene, M.D., to Miss Louise Shandorf, both of Albany, N. Y., August 30.

Edward C. Kottcamp, M.D., to Miss Blanche I. Dolson, both of Philadelphia, September 6.

D. E. Singleton, M.D., to Miss Maude Wainwright, both of Shelbina, Mo., September 19.

Ross Lee Moter, M.D., Browns, Ill., to Miss Grace Jones of Princeton, Ind., September 13.

Robert B. Hixson, M.D., to Miss Minerva Barker, both of Cambridge, Minn., September 13.

Clarence A. Good, M.D., St. Joseph, Mo., to Miss Sophie Evans of Erie, Pa., September 15.

Roy E. Mason, M.D., Sapulpa, I. T., to Miss Elizabeth Patee of La Grange, Mo., September 12.

Joseph S. Phalan, M.D., to Miss Margaret M. Fitzpatrick, both of Philadelphia, September 11.

Edgar Allen P. Jones, M.D., Wingate, Md., to Miss Anna B. Patterson, at Baltimore, September 21.

Fred R. Lintleman, M.D., Harlan, Iowa, to Miss Faith Gertrude Willis of Iowa City, Iowa, September 12.

Daniel A. Gray, M.D., Little Rock, Ark., to Miss Annie Statlings of Salisbury, N. C., September 12.

Byron J. Arnold, M.D., Tyler, Texas, to Miss Lessie V. Richmond of Little Rock, Ark., September 14.

Charles A. Sylvia, M.D., Providence, R. I., to Miss Palmira S. Lemos of New Bedford, Mass., September 11.

Roderick D. Kennedy, M.D., Globe, Ariz., to Miss Harriet Lawton Hudson of Mukwonago, Wis., August 15.

William B. Caldwell, M.D., Monticello, Ill., to Miss Anna Olentine of Paxton, Ill., at Sioux City, S. D., September 20.

Walter Vose Gulick, M.D., Rochester, Minn., to Miss Eleanor Frances Brooks of Boston, at Grafton, Ontario, September 19.

Deaths

Frederick Augustus Baldwin, M.D. Bellevue Hospital Medical College, New York City, 1881, a member of the American Medical Association, New York State Medical Association, and New York County Medical Association; from 1883 to 1886, on the staff of the Eastern Dispensary, New York City; from 1884 to 1885 attending surgeon to the Outdoor Department of Bellevue Hospital; from 1885 to 1889 assistant to the late Dr. Valentine J. Mott, died at his home in New York City September 21, after an illness of six months, aged 59.

Henry L. Day, M.D. University of Buffalo (N. Y.) Medical Department, 1860, a member of the American Medical Association, state, county and local medical societies; a member of the ninth International Medical Congress; assistant surgeon of the Seventy-eighth New York Volunteer Infantry in the Civil War; for 24 years a prominent practitioner and leading citizen of Eau Claire, Wis.; twice mayor of that city, died at his home September 16 from pleurisy, after an illness of a month, aged 66.

Joseph Langford Wever, M.D. Albany (N. Y.) Medical College, 1852, surgeon of the Seventh Kansas Volunteer Cavalry during the Civil War; a pioneer of Leavenworth; prominent in educational matters; for 20 years a member and president of the local school board, and for six years a regent of the state university, died at his home from senile debility September 11, after a gradual decline of a year and a half, aged 80.

Theodore Hopkins, M.D. Toronto (Ont.) Medical College, contract surgeon United States Army from 1850 to 1860; during the Civil War surgeon in the army; in active practice for more than 40 years, died at his home in Niles, Mich., September 10, from peritonitis following cholera morbus, after an illness of one week, aged 84.

Cyrus S. Bulhand, M.D. College of Physicians and Surgeons, Keokuk, Iowa, 1874, a pioneer of Cass County, Mich., died at his home in Union, Mich., September 11 from cancer of the stomach, aged 59. The Cass County Medical Society passed resolutions of regret and respect.

Joseph Riley Smith, M.D. Transylvania University Medical Department, Lexington, Ky., 1841, the first white child born in Jefferson County, Ala., and for many years a prominent physician of Birmingham, died at the home of his son in Elyton, Ala., August 30, aged 87.

Guy C. M. Godfrey, M.D. College of Physicians and Surgeons, Baltimore, 1892, captain and assistant surgeon United States Army, committed suicide by shooting himself at his quarters in Fort McPherson, Atlanta, Ga., September 24, aged 34.

David Leonidas Norris, M.D. Jefferson Medical College, Philadelphia, 1897, physician for the Bacon-Nolan Hardwood Company, Chaney, Miss., died at that place September 4 from malarial fever, after an illness of about ten days, aged 33.

Lafayette Balcom, M.D. University of Buffalo (N. Y.) Medical Department, 1864, of Buffalo, N. Y., died at the home of his sister in Detroit, Mich., September 14, from nervous collapse following septicemia, after a long illness, aged 67.

Charles Smith, M.D. Missouri Medical College, St. Louis, 1879, an orig settler and a pioneer practitioner of Guthrie, Okla., di his home in that city September 9 from cirrhosis of after a protracted illness, aged 48.

of nutrition. Certain die
less widely adopted, but a

under which the data were collected leads to the conclusion that the standards in question have a very uncertain value. Especially do we need more definite knowledge of the true physiologic necessities of the body for proteid or albuminous foods which we are accustomed to look on as the essential foods. The author presents results of extensive experiments and gives brief summaries of the results. The subjects of the experiments represented three quite distinct classes—professional men, soldiers (volunteers from the hospital corps of the United States Army), and athletes. Accepted dietaries, as those of Voit, Moleschott, Ranke, Forster, Atwater and Schmidt, give the minimal daily proteid requirement for the average male adult at moderate work as 100 grammes to 134 grammes. Is it not possible that the accepted dietary standards are too high? The author has always maintained that man is disposed to eat far more than the needs of the body require, but his active interest in this problem was aroused especially by his observations of Mr. Fletcher (first observed by Dr. Van Someren, then by Michael Foster and later by the author), and the marked physiologic economy that Fletcher was able to practice not only without detriment, but with great gain to the body as regards strength, vigor and endurance, coupled with an apparent resistance to disease. The first experiments were on five professional men connected with Yale University as professors and instructors, the author himself being one of the subjects. Dr. Chittenden reduced his ingested proteid to nearly one-third that prescribed by Voit and says regarding his experience with the light diet: "Health, strength, mental and physical vigor, have been maintained unimpaired and there is a growing conviction that in many ways there was a distinct improvement in both physical and mental condition. Greater freedom from fatigue, greater aptitude for work and greater freedom from minor ailments have gradually become associated in the writer's mind with this lowered proteid metabolism and general condition of physiologic economy." The author found that other professional men gave substantially the same results, and summarizes his experiments as follows: "The professional man can safely practice a physiologic economy in the use of proteid food equal to the saving of one-half to two-thirds of the amount called for by existing dietary standards, and this without increasing the amount of non-nitrogenous food consumed." In summarizing the results obtained from experiments on soldiers the author says: "The subjects lived without discomfort for a period of five months on amounts of proteid food not more than one-half that called for by ordinary standard dietaries, and this without increasing the amount of non-nitrogenous food. . . . The subjects were less conscious of fatigue than formerly. . . . All the men have been well and remarkably free from colds and other minor ailments throughout the experiments." The author found that his group of athletes yielded substantially the same results as the other groups. The work is a most valuable contribution to the literature of nutrition.

The Surgical Assistant. A Manual for Students, Practitioners, Hospital Internes and Nurses. By W. M. Brickner, B.S., M.D., with 123 Original Illustrations. Cloth. Pp. 363. Price $2.00. New York: International Journal of Surgery Co.

Few books on surgery devote much space to the duties of the surgical assistant; Brickner's work therefore fills a want. The first chapter deals with the conduct of the assistant and his relations with the surgeon and the patient, and lays emphasis on the fact that the assistant must display considerable tact, especially in answering the patient's questions and in calling the surgeon's attention to details which he may have overlooked. Chapter 2 deals with the duties of hospital internes. Subsequent chapters give in detail the duties of an assistant in the various operations, whether in hospitals or in private houses, and directions are also given for preparing an operating room. Although this latter duty is usually relegated to a nurse and seldom has to be attended to by the assistant; he often must supervise it and see that it is properly done. Twenty-one pages are devoted to the duties of the anesthetist and to the various methods of inducing anesthesia. In it Brickner calls attention to the necessity for good judgment on the part of the anesthetist in order to determine at times whether the patient is "coming out" and needs more of the anesthetic or is getting too much. The book is well illustrated, and an appendix contains directions for the preliminary preparation and postoperative care of patients, methods of preparing suture materials and gauze, and an illustrated list of instruments.

Index-Catalogue of the Library of the Surgeon-General's Office, United States Army. Second Series. Vol. X. M.—Mnikhovski. Cloth. Pp. 935. Washington: Government Printing Office. 1905.

This is a welcome addition to the volumes already out. We have commented, in mentioning the appearance of the other volumes, on the excellent typographic arrangement, making the volume so convenient for consultation. This volume contains the important references of: Man, Marriage, Massage, Materia Medica, Measles, Medicine, Melancholia, Meningitis, Mercury, Metabolism, Microscope, Milk and many others, which indicate the value of this volume alone as an index medicus. The word "Medicine" alone covers 270 pages of closely printed references.

Psychological Medicine. A Manual on Mental Diseases for Practitioners and Students. By M. Craig, M.A., M.D. Cloth. Pp. 449. Price, $4.00 net. Philadelphia: P. Blakiston's Son & Co. 1905.

This is a systematic work on psychiatry, beginning with a chapter (18 pages) on normal psychology, embracing a consideration of the different forms of mental disease and ending with a chapter on treatment (39 pages). There is also a chapter of considerable size on general symptomatology, others on feigned insanity, relation of insanity with law, sleeplessness, etc. The author is a thoughtful, competent alienist of wide experience, but he has not found the secret of lucid, consecutive writing. No doubt he himself has a clear appreciation of the fundamental lines, the dominating traits of mental maladies, but he fails to bring them into salient relief. He lacks the power of graphic description. The book and the chapters are systematically divided, the paragraphs are not. For instance, under physical symptoms of alcoholism (page 191), is given a hodge-podge of symptoms; each one correct, but all enumerated in a hit-and-miss way which must be confusing to the student or general practitioner. Another feature which detracts from the value of the work as a text-book is an excess or rather malposition of qualification. The word may is sadly overworked. Frequently the author starts a description with this modifier. For example, on page 150 he begins a presentation of the symptoms of the catatonic form of dementia præcox by saying: "This type of dementia præcox may develop in an insidious manner," and then not only fails to state what the rule of onset is, but entirely neglects to say whether it ever develops in any other way.

All this is not to say that the work is poor, for it is not. In the main, it is a perfectly safe guide, there are very few omissions and we have discovered no errors of fact. Not only is the chapter on treatment good, but through the book this branch of psychiatry receives fuller and better attention than it does in most text-books. The careful and judicious consideration of prognosis will also be a boon to many a beginner and general practitioner. We distinctly approve the insertion of a chapter on epochal insanities—puerperal insanity, climacteric insanity, senile insanity. While they present nothing characteristic in form or nature, the circumstances and some features make it clinically practical to consider them separately. The chapter on general paresis is good. Here the author's experience and good judgment outweighs his rather prosy and disjointed, even distrait, style. The chapters on the relationship of insanity with law and on case-taking will prove most useful to those of limited experience with the insane. The subjects epilepsy and insanity and hysteria and insanity are well done from the viewpoint of the asylum physician. In matters strictly neurologic, the author is scarcely *au fait*. For instance, he says (page 269) that the Babinski sign is found in paralysis from "organic disease," but fails even to intimate that it is only in organic disease of the pyramidal tract that the sign may be elicited. Further indicative of neurologic delinquency is the section on traumatic neuroses. It is crude to a degree. The book is well printed on excellent paper and the illustrations are fine.

Charles A. Sylvia, M.D., Providence, R. I., to Miss Palmira S. Lemos of New Bedford, Mass., September 11.

Roderick D. Kennedy, M.D., Globe, Ariz., to Miss Harriet Lawton Hudson of Mukwonago, Wis., August 15.

William B. Caldwell, M.D., Monticello, Ill., to Miss Anna Olentine of Paxton, Ill., at Sioux City, S. D., September 20.

Walter Vose Gulick, M.D., Rochester, Minn., to Miss Eleanor Frances Brooks of Boston, at Grafton, Ontario, September 19.

Deaths

Frederick Augustus Baldwin, M.D. Bellevue Hospital Medical College, New York City, 1881, a member of the American Medical Association, New York State Medical Association, and New York County Medical Association; from 1883 to 1886, on the staff of the Eastern Dispensary, New York City; from 1884 to 1885 attending surgeon to the Outdoor Department of Bellevue Hospital; from 1885 to 1889 assistant to the late Dr. Valentine J. Mott, died at his home in New York City September 21, after an illness of six months, aged 59.

Henry L. Day, M.D. University of Buffalo (N. Y.) Medical Department, 1860, a member of the American Medical Association, state, county and local medical societies; a member of the ninth International Medical Congress; assistant surgeon of the Seventy-eighth New York Volunteer Infantry in the Civil War; for 24 years a prominent practitioner and leading citizen of Eau Claire, Wis.; twice mayor of that city, died at his home September 16 from pleurisy, after an illness of a month, aged 66.

Joseph Langford Wever, M.D. Albany (N. Y.) Medical College, 1852, surgeon of the Seventh Kansas Volunteer Cavalry during the Civil War; a pioneer of Leavenworth; prominent in educational matters; for 20 years a member and president of the local school board, and for six years a regent of the state university, died at his home from senile debility September 11, after a gradual decline of a year and a half, aged 80.

Theodore Hopkins, M.D. Toronto (Ont.) Medical College, contract surgeon United States Army from 1850 to 1860; during the Civil War surgeon in the army; in active practice for more than 40 years, died at his home in Niles, Mich., September 10, from peritonitis following cholera morbus, after an illness of one week, aged 84.

Cyrus S. Bulhand, M.D. College of Physicians and Surgeons, Keokuk, Iowa, 1874, a pioneer of Cass County, Mich., died at his home in Union, Mich., September 11 from cancer of the stomach, aged 59. The Cass County Medical Society passed resolutions of regret and respect.

Joseph Riley Smith, M.D. Transylvania University Medical Department, Lexington, Ky., 1841, the first white child born in Jefferson County, Ala., and for many years a prominent physician of Birmingham, died at the home of his son in Elyton, Ala., August 30, aged 87.

Guy C. M. Godfrey, M.D. College of Physicians and Surgeons, Baltimore, 1892, captain and assistant surgeon United States Army, committed suicide by shooting himself at his quarters in Fort McPherson, Atlanta, Ga., September 24, aged 34.

David Leonidas Norris, M.D. Jefferson Medical College, Philadelphia, 1897, physician for the Bacon-Nolan Hardwood Company, Chaney, Miss., died at that place September 4 from malarial fever, after an illness of about ten days, aged 33.

Lafayette Balcom, M.D. University of Buffalo (N. Y.) Medical Department, 1864, of Buffalo, N. Y., died at the home of his sister in Detroit, Mich., September 14, from nervous collapse following septicemia, after a long illness, aged 67.

Charles Smith, M.D. Missouri Medical College, St. Louis, 1879, an orig[illegible] settler and a pioneer practitioner of Guthrie, Okla., di[illegible] his home in that city September 9 from cirrhosis of [illegible] after a protracted illness, aged 48.

[illegible] **M.D.** Western Pennsylvania Medical [illegible] son of the late Dr. John Milton [illegible] Pittsburg, September 16,

20,000 [illegible] been issued but [illegible] executed. [illegible] time to time been made to the govern[illegible] enforcing the law. The home secretary has [illegible] matum which has caused some consternation. [illegible] Scotland, 1841, formed the watch committee that unless the police ta[illegible] Halifax, N. to execute the warrants he will withdraw the gover[illegible] illness grant toward the aid of the police, which last year amount[illegible] to $30,000. Accordingly the town council instructed the chief constable to put the act into operation. But apart from the

ville April 22 from heart disease, after an illness of a year, aged 72.

John A. Wilcox, M.D. Medical School of Maine at Bowdoin College, Brunswick, 1872, Wakefield, R. I., was taken suddenly ill at Narragansett Pier August 28, and died August 30, aged 58.

Thomas Jefferson Wright, M.D. St. Louis Medical College, 1866, died recently at his home in Fort Smith, Ark., from chronic intestinal trouble, after a prolonged illness, aged 69.

E. H. Files, M.D. St. Louis College of Physicians and Surgeons, 1901, of Fallis, Okla., died suddenly at Hot Springs, Ark., September 13, from rheumatic endocarditis.

Alfred A. Dreher, M.D. University of Wooster Medical Department, Cleveland, Ohio, 1884, died at his home in Cleveland, September 19, after a short illness, aged 46.

James R. Walker, M.D. Toledo (Ohio) Medical College, 1891, died at his home in Walbridge, Ohio, September 12 from nephritis, after a long illness, aged 45.

George W. Ellis, M.D. Department of Medicine of the University of Pennsylvania, Philadelphia, 1861, of Philadelphia, died in Paris, France, June 5.

Louis Henry Schultz, M.D. Baunscheidt College, Bonn, Germany, 1857, of Philadelphia, died at Atlantic City August 28 from heart disease, aged 71.

Wilson Stuve, M.D. St. Louis Medical College, 1882, died at his home in Oklahoma City, Okla., August 31, from heart disease, aged 46.

Daniel H. Hanks, M.D. New York City, 1874, died at his home in Ballston Lake, N. Y., September 3, aged 81.

William M. Brown, M.D. Rush Medical College, Chicago, 1881, died at his home in Chicago, September 14.

Deaths Abroad.

Thomas John Barnardo, M.D., the well-known founder and director of institutions for destitute children, whereby more than 55,000 orphan waifs have been rescued from poverty and crime, died at his home in London, Eng., September 20 from angina pectoris after a short illness, aged 60. He was born in England, received his preliminary education in private schools, and subsequently pursued medical studies in London, Edinborough and Paris. He was licensed in medicine in 1876 and obtained the degree of F.R.C.S. Edin., in 1879. In 1886, while in the London Hospital, he first had his attention directed to the condition of the street waifs of London, and the amelioration of their condition he afterward made his life work, placing thousands of them in comfortable homes or on farms in England and in the Dominion of Canada, New Zealand and Australia. In 1885 he was awarded the diploma and medal of the Société Nationale d'Encouragement de Bien of Paris. He was commonly known as the "foster father of nobody's children." He was a member of the British Medical Association, and was consulting surgeon of the Hospital for Sick Children, Stepney.

P. Schubert, M.D., a well-known ophthalmologist and aurist of Nuremberg, prominent for his efforts to promote school hygiene, died at Nuremberg, August 25, aged 56. He was one of the organizers of the first International Congress of School Hygiene held at Nuremberg last year.

B. H. Laehr, M.D. of Zehlendorf, called the Nestor of German alienists, died August 25, aged 85. His sanitarium Schweizerhof, for nervous and mental affections in women, is world-famous, and recently celebrated its semi-centennial.

Dr. Borchert, assistant at the Institute of Physiology at Berlin, committed suicide by taking sublimate when he learned that his application for the post of privat docent had been rejected.

A. J. Kunkel, M.D., professor of pharmacology at Würzburg and author of important contributions to toxicology and hygiene, died at Würzburg, August 23, aged 57.

Book Notices

Physiological Economy in Nutrition, with special reference [illegible] Healthy Man. An Ex- [illegible] Ph.D., LL.D., Sc.D., [illegible] New York: Frederick [illegible]

There is no subject of greater physiologic importance or of greater moment for the welfare of the human race than that of nutrition. Certain dietetic standards have been more or less widely adopted, but a careful scrutiny of the conditions under which the data were collected leads to the conclusion that the standards in question have a very uncertain value. Especially do we need more definite knowledge of the true physiologic necessities of the body for proteid or albuminous foods which we are accustomed to look on as the essential foods. The author presents results of extensive experiments and gives brief summaries of the results. The subjects of the experiments represented three quite distinct classes—professional men, soldiers (volunteers from the hospital corps of the United States Army), and athletes. Accepted dietaries, as those of Voit, Moleschott, Ranke, Forster, Atwater and Schmidt, give the minimal daily proteid requirement for the average male adult at moderate work as 100 grammes to 134 grammes. Is it not possible that the accepted dietary standards are too high? The author has always maintained that man is disposed to eat far more than the needs of the body require, but his active interest in this problem was aroused especially by his observations of Mr. Fletcher (first observed by Dr. Van Someren, then by Michael Foster and later by the author), and the marked physiologic economy that Fletcher was able to practice not only without detriment, but with great gain to the body as regards strength, vigor and endurance, coupled with an apparent resistance to disease. The first experiments were on five professional men connected with Yale University as professors and instructors, the author himself being one of the subjects. Dr. Chittenden reduced his ingested proteid to nearly one-third that prescribed by Voit and says regarding his experience with the light diet: "Health, strength, mental and physical vigor, have been maintained unimpaired and there is a growing conviction that in many ways there was a distinct improvement in both physical and mental condition. Greater freedom from fatigue, greater aptitude for work and greater freedom from minor ailments have gradually become associated in the writer's mind with this lowered proteid metabolism and general condition of physiologic economy." The author found that other professional men gave substantially the same results, and summarizes his experiments as follows: "The professional man can safely practice a physiologic economy in the use of proteid food equal to the saving of one-half to two-thirds of the amount called for by existing dietary standards, and this without increasing the amount of non-nitrogenous food consumed." In summarizing the results obtained from experiments on soldiers the author says: "The subjects lived without discomfort for a period of five months on amounts of proteid food not more than one-half that called for by ordinary standard dietaries, and this without increasing the amount of non-nitrogenous food. . . . The subjects were less conscious of fatigue than formerly. . . . All the men have been well and remarkably free from colds and other minor ailments throughout the experiments." The author found that his group of athletes yielded substantially the same results as the other groups. The work is a most valuable contribution to the literature of nutrition.

The Surgical Assistant. A Manual for Students, Practitioners, Hospital Internes and Nurses. By W. M. Brickner, B.S., M.D., with 123 Original Illustrations. Cloth. Pp. 363. Price $2.00. New York: International Journal of Surgery Co.

Few books on surgery devote much space to the duties of the surgical assistant; Brickner's work therefore fills a want. The first chapter deals with the conduct of the assistant and his relations with the surgeon and the patient, and lays emphasis on the fact that the assistant must display considerable tact, especially in answering the patient's questions and in calling the surgeon's attention to details which he may have overlooked. Chapter 2 deals with the duties of hospital internes. Subsequent chapters give in detail the duties of an assistant in the various operations, whether in hospitals or in private houses, and directions are also given for preparing an operating room. Although this latter duty is usually relegated to a nurse and seldom has to be attended to by the assistant; he often must supervise it and see that it is properly done. Twenty-one pages are devoted to the duties of the anesthetist and to the various methods of inducing anesthesia. In it Brickner calls attention to the necessity for good judgment on the part of the anesthetist in order to determine at times whether the patient is "coming out" and needs more of the anesthetic or is getting too much. The book is well illustrated, and an appendix contains directions for the preliminary preparation and postoperative care of patients, methods of preparing suture materials and gauze, and an illustrated list of instruments.

Psychological Medicine. A Manual on Mental Diseases for Practitioners and Students. By M. Craig, M.A., M.D. Cloth. Pp. 449. Price, $4.00 net. Philadelphia: P. Blakiston's Son & Co. 1905.

This is a systematic work on psychiatry, beginning with a chapter (18 pages) on normal psychology, embracing a consideration of the different forms of mental disease and ending with a chapter on treatment (39 pages). There is also a chapter of considerable size on general symptomatology, others on feigned insanity, relation of insanity with law, sleeplessness, etc. The author is a thoughtful, competent alienist of wide experience, but he has not found the secret of lucid, consecutive writing. No doubt he himself has a clear appreciation of the fundamental lines, the dominating traits of mental maladies, but he fails to bring them into salient relief. He lacks the power of graphic description. The book and the chapters are systematically divided, the paragraphs are not. For instance, under physical symptoms of alcoholism (page 191), is given a hodge-podge of symptoms; each one correct, but all enumerated in a hit-and-miss way which must be confusing to the student or general practitioner. Another feature which detracts from the value of the work as a text-book is an excess or rather malposition of qualification. The word may is sadly overworked. Frequently the author starts a description with this modifier. For example, on page 150 he begins a presentation of the symptoms of the catatonic form of dementia præcox by saying: "This type of dementia præcox may develop in an insidious manner," and then not only fails to state what the rule of onset is, but entirely neglects to say whether it ever develops in any other way.

All this is not to say that the work is poor, for it is not. In the main, it is a perfectly safe guide, there are very few omissions and we have discovered no errors of fact. Not only is the chapter on treatment good, but through the book this branch of psychiatry receives fuller and better attention than it does in most text-books. The careful and judicious consideration of prognosis will also be a boon to many a beginner and general practitioner. We distinctly approve the insertion of a chapter on epochal insanities—puerperal insanity, climacteric insanity, senile insanity. While they present nothing characteristic in form or nature, the circumstances and some features make it clinically practical to consider them separately. The chapter on general paresis is good. Here the author's experience and good judgment outweighs his rather prosy and disjointed, even distrait, style. The chapters on the relationship of insanity with law and on case-taking will prove most useful to those of limited experience with the insane. The subjects epilepsy and insanity and hysteria and insanity are well done from the viewpoint of the asylum physician. In matters strictly neurologic, the author is scarcely *au fait*. For instance, he says (page 269) that the Babinski sign is found in paralysis from "organic disease," but fails even to intimate that it is only in organic disease of the pyramidal tract that the sign may be elicited. Further indicative of neurologic delinquency is the section on traumatic neuroses. It is crude to a degree. The book is well printed on excellent paper and the illustrations are fine.

Queries and Minor Notes

Anonymous Communications will not be noticed. Queries for this column must be accompanied by the writer's name and address, but the request of the writer not to publish name or address will be faithfully observed.

CONTRACT SERVICE FOR ACCIDENT INSURANCE.

Oconto, Wis., Sept. 22, 1905.

To the Editor:—This city has about 6,000 inhabitants. The place has three saw mills, several planing mills and a pail factory. There are eight physicians in the place. The city has no hospital facilities. The physicians here call themselves just plain "physicians and surgeons." We have no specialists. Everyone of these physicians expects to do a certain amount of the surgical work called for, due to accidents in the above-named mills, for individuals who are otherwise considered as belonging to their respective clientele. Under such circumstances would it be an infringement of professional ethics if I signed the enclosed blank contract, and the company with such signed contract succeeded in controlling the accident cases and liabilities connected therewith of the various mill companies located in this city and thus in a manner directing the surgery into the hands of the subscriber, he being then the "contract surgeon"? Please give me your opinion. Kindly return the blank contract to me. How would this compare with contract lodge practice. C. W. Stoelting.

The contract referred to is of a well-known life insurance company and witnesses as follows:

> That whenever the said company issues a policy of liability insurance covering business operations conducted within such territorial limits as may be assigned to the doctor, and which provides therein for the furnishing of full medical and surgical attendance to persons injured as a result of the operations covered and contemplated by said contract of insurance and during its full term, then, in that event, the said doctor agrees to furnish such medical and surgical service and reports as may be required.
>
> It is further agreed on the part of the doctor that he will, himself, provide this service or furnish competent and reputable substitutes subject to call at all reasonable hours, and in all cases within reasonable and convenient access to the locations within or in the vicinity of the City of Oconto, Wis., where said business operations may be conducted.
>
> Said company agrees promptly to notify the said doctor on its issuance of any such contracts with complete information as to the name and location of the individual, firm or corporation assured thereunder, and said doctor will immediately designate such of his substitutes as will act in his absence or stead in the [illegible]ance of the services required to be rendered under each [illegible]tract of insurance.
>
> [illegible]urther agreed that said doctor shall use his best efforts [illegible]uence to arrange for the furnishing of ambulance and [illegible]al services which may be necessary in connection with injuries covered under said contract as will result in a [illegible]imum of expense to the firm or individual who shall become [illegible]sible for the cost of such ambulance or hospital service.
>
> n consideration of the foregoing, and as full compensation or all of the services so to be rendered, either by himself or his substitutes it is hereby agreed, that the said doctor shall receive 10 per cent. of the gross earned premiums on all contracts so written, which compensation shall be payable as follows: Five per cent. on the estimated premium, payable the first of the month succeeding the date of the collection of said premium by the company, the balance, making the total equivalent to 10 per cent. of the gross earned premium, shall be payable on the first of the month following the ascertaining and collection of said earned premium.
>
> It is further agreed that this contract may be terminated at the option of either party thereto on thirty days written notice, except that the said doctor agrees at the option of the company to render such full medical treatment of injuries covered by any policy issued prior to such notification until the expiration of such policy.
>
> It is further specified that during the continuance of this agreement, the doctor shall not enter into any contract of a similar nature with any *other insurance company.*

Answer.—From the broad view-point of the general professional welfare there can be but one answer to this letter. The signing of such a contract is, in the widest sense, "unprofessional conduct." Everywhere the profession should agree never to accept work under such conditions. The fees offered are purely contingent; and, according to the good or the ill fortune of the mill hands and varying with the success of the insurance company's agent, the fees may be utterly inadequate or, perchance, too high. In any event the physician's remuneration for his work is wholly speculative. A more objectionable arrangement would be difficult to conceive. On the practical side our correspondent is entitled to *sympathy and counsel.* No doubt he feels that if he does not accept this contract one of his competitors will. Herein lies the value of a united profession working together. Let all eight of the physicians in the place meet and agree to accept no such contract. If there is already a county society, so much the better, but if not either one should be organized or these eight physicians should at once as a preliminary move agree to stand against this form of *contract* practice. This is the remedy. It is wholly effectual. Under such conditions the company must either withdraw from caring for its employes in the town or else must arrange to deal fairly with physicians. The ethics of the case is *perfectly clear.* To accept this contract, means essentially that the contracting physician underbids his competitors in the effort to take from them their work. On no other presumption could this form of liability *insurance be* made profitable to the mill-owners who take out such policies. Medical men must unite in the effort to put an end to such methods.

CHOICE OF LIGATURES.

Waverly, Mo., Aug. 29, 1905.

To the Editor:—What are the main indications for use of silk, catgut and silkworm gut ligatures? What is the best ligature material for bleeding vessels? In a tenorrhaphy where much strain comes would silk do best, and would a flexed position be proper for dressing?

Answer.—There are no absolute contraindications to the use of fine silk ligatures in clean wounds, though it is probably better practice to employ catgut. The latter is almost positively indicated in the presence of certain, or even possible, suppuration since its absorption within a few days eliminates a foreign body and, therefore, a *locus minoris resistantiæ.* Silkworm gut is applicable to every form of wound closure (unless buried) as interrupted, tension or continuous subcutaneous sutures. As ligature material, the use of silkworm gut is rarely, if ever, justified. A tendon suture under tension should always be avoided, when necessary, by some form of plastic operative lengthening of the tendon or of the muscle itself. Silk, or better, kangaroo tendon or chromicized catgut, would serve as suture material, but so applied as to give direction to the tendon ends rather than needlessly to make accurate approximation requiring even a little tension. Fixation in any exaggerated position, unless as an over-correction of a pre existing deformity, as a rule, is to be avoided.

LAPAROTOMY UNDER LOCAL ANESTHESIA IN AGED PATIENT.

Manchester, N. H., Sept. 20, 1905.

To the Editor:—Noticing Dr. Igel's report of an operation on a patient 72 years old, I would like to mention one. In a man aged 78 there was an irreducible inguinal omental hernia, on the right side, which had been strangulated for 24 hours. The patient was removed about four miles, in an ambulance, to a local hospital, and under subcutaneous injection of sterile water, the sac was opened. The ring was cut, the omentum tied off, and the canal closed. He was allowed up on the eighth day; walked about the next day, and went home on the thirteenth day. A. H. Wheat.

State Boards of Registration

COMING EXAMINATIONS.

Central District Indian Territory Board of Medical Examiners, South McAlester, October 2. Secretary, W. B. Caldwell, Hugo.

Utah State Board of Medical Examiners, Salt Lake City, October 2. Secretary, R. W. Fisher, Salt Lake City.

Board of Medical Examiners of Arizona, Phoenix, October 2-3. Secretary, A. Martin, Phoenix.

Idaho State Board of Medical Examiners, Boise, October 3. Secretary, J. L. Conant, Jr., Genesee.

Indiana Board Medical Registration and Examination, State House, Indianapolis, October 3. Secretary, W. T. Gott, Crawfordsville.

Board of Medical Examiners of Montana, The Capitol, Helena, October 3. Secretary, W. C. Riddell, Helena.

North Dakota State Medical Examining Board, Grand Forks, October 3. Secretary, H. M. Wheeler, Grand Forks.

Minnesota State Board of Medical Examiners, Old Capitol Building, St. Paul, October 3-5. Secretary, C. J. Ringnell, Minneapolis.

Rhode Island State Board of Health, State House, Providence, October 5-6. Secretary, G. T. Swarts, Providence.

Regular Board of Medical Examiners of Georgia, The Capitol, Atlanta, October 9. Secretary, F. D. Paterson, Cuthbert.

Michigan State Board of Registration in Medicine, Capitol Building, Lansing, October 10. Secretary, B. D. Harison, Sault Ste. Marie.

State Medical Board of the Arkansas Medical Society, Little Rock, October 10. Secretary, J. P. Runyan, Little Rock.

Board of Medical Examiners of State of Florida, Jacksonville, Oct. 10-11. Secretary J. D. Fernandez, Jacksonville.

Kansas State Board of Medical Registration and Examination, State House, Topeka, October 10-11. Secretary, G. F. Johnston, Lakin.

State Board of Medical Registration of Vermont, Y. M. C. A. Hall, Burlington, October 10-12. Secretary, W. S. Nay, Underhill.

Board of Medical Supervisors of Washington, D. C., Washington D. C., October 12. Secretary, W. C. Woodward, Washington, D. C

Board of Medical Examiners of State of Texas, San Antonio, October 17. Secretary, T. T. Jackson, San Antonio.

State Board of Medical Examiners of New Jersey, Trenton, October 17-18. Secretary, E. L. B. Godfrey, Camden.

State Board of Health of Illinois, The Great Northern Hotel, Chicago, October 18. Secretary, J. A. Egan, Springfield.

Louisiana State Board, New Orleans, October 20-21. Secretary, F. A. Larue, New Orleans.

Next Florida Examination.—The fall examinations of the Regular Board of Medical Examiners of the State of Florida will be held at Jacksonville, October 10 and 11, at the auditorium of the Board of Trade, corner of Main and Adams streets. Applications for examination must be made in person to the secretary of the board so that he can inspect the diploma of the applicant, and register him on the day prior to the examination, or in the week preceding. Any information desired will be furnished the applicant when he registers with the secretary, at his office, 28 West Ashley Street. J. D. Fernandez, M.D., Secretary, Jacksonville, Fla.; H. E. Palmers, M.D., President, Tallahassee, Fla.

Maryland June Report.—Dr. J. McP. Scott, secretary of the Board of Medical Examiners of Maryland, reports the examination held June 21-24, 1905. Students who had completed the second year were granted an examination in anatomy, chemistry, materia medica and physiology. Their ratings were carried forward and will be made a part of their final examination. The total number of candidates examined was 147, of whom 24 were re-examined in the subjects in which they had previously failed, and 28 failed, while 22 were second-year students. Graduates of the following colleges passed:

The following questions were asked:

PASSED.

University of Maryland, (1904) 77; (1905) the grade of 75 was reached by one; 76 was reached by two; 77 by one; 78 by three; 79 by one; 80 by two; 82 and 83 by two each; 84 by three; 85 by four; 86 by two; 87 by one; 88 by two; 89 and 91 by one each.
University of Pennsylvania........................(1902) 91
University of Virginia ....(1905) 86
College of P. and S., Baltimore, (1901) 75; (1904) 84; (1905) the grade of 76 was reached by one; 80 was reached by two; 81 and 83 by one each; 84 by three; 88 by one.
Woman's Med. Coll. ....(1905) 79, 83
Maryland Med. Coll., (1904) 88; (1905) the grades of 75 and 78 were reached by one each; 80 was reached by three; 85 by one.
Baltimore Med. Coll., (1905) 76, 78, 79, 80, 80, 83, 84, 86, 92.
Johns Hopkins University (1900) 88; (1905) 78, 83, 85, 86, 87, 88, 90, 92, 94.
Georgetown University ....(1905) 87
George Washington University ....(1905) 89

The following questions were asked:

CHEMISTRY.

1. (a) Define: Atom; molecule; radical; valence. (b) Define: Acids; bases; salts. Give the general properties of each with an example. (Applicant must answer either one (a) or (b) of the questions above, but must not answer both.)
2. Give formula for "hydrogen peroxid" and the reasons for its use in surgery as a disinfectant and antiseptic.
3. Describe bismuth subnitrate and explain the dark color of the stools following its therapeutic use. Name its most dangerous impurity and give test for detection of same.
4. Give formula and general physical properties of chloroform. Construct its "graphic (structural) formula" and from this show what relation it bears to the paraffin group of hydrocarbons, say marsh gas CH_4.
5. What is the chemical constitution of urea? Give approximate amount normally excreted in 24 hours, and a method for its quantitative determination.
6. Give in detail a test for the detection of lactic acid in a specimen of the gastric contents.

OBSTETRICS.

1. Describe the placental circulation.
2. Give the best method of managing a shoulder presentation.
3. Give management of a normal labor in its three stages.
4. Describe anteversion and anteflexion, also retroversion and retroflexion.
5. Mention some of the uses of vaginal tampons and how they should be prepared and introduced.
6. How would you manage a case of prolapsed funis.

MATERIA MEDICA.

1. What do you understand by the incompatibility of drugs? Give example.
2. In what particulars are opium and belladonna synergists and antagonists?
3. Name three of the principal alkaloids of opium. Give dose of each.
4. Name the official preparations of zinc. Dose and use of each.
5. What is the composition of Donovan's solution?
6. What is the source of potassium? Name four of the principal preparations, their use and dose?

THERAPEUTICS.

1. Give the symptoms and treatment of lead poisoning.
2. Give the symptoms you would expect to find when an over dose of chloral hydrate had been taken and the treatment of such a case.
3. What are the therapeutic uses of digitalis and the contraindications for its use?
4. Differentiate the coma of alcoholism, apoplexy, opium and uremia: give treatment of each.
5. Quinin: Indications for, and mode of administration of quinin as an antiperiodic, an antipyretic, and oxytocic How eliminated?
6. Therapeutics of heat.

PRACTICE.

1. Define arteriosclerosis, diabetes mellitus, tenia solium, and dermatitis.
2. Give diagnosis and treatment of angina pectoris.
3. Give differential diagnosis between malarial and typhoid fevers and treatment of each.
4. Give the symptoms of locomotor ataxia; its causes and treatment.
5. Give differential diagnosis between scarlet fever and measles. the treatment and sequelæ of each.
6. Name the symptoms of cerebral hemorrhage.

SURGERY.

1. Give the differential diagnosis of a fracture of the neck of the humerus from a downward dislocation of the humerus, and give in detail a method of treating each condition.
2. Give the differential diagnosis between perinephritic abscess and appendicitis.
3. Give causes and symptoms of adenitis.
4. Give symptoms and treatment of dislocation of radius at elbow.
5. Describe an approved method for the removal of foreign bodies from the ear.
6. Describe an aseptic operation in any region you wish.

PHYSIOLOGY.

1. (a) What is the composition of the saliva? (b) What is its most important function? (c) What action has atropin, pilocarpin and nicotin on the salivary glands and their secretion?
2. What is the difference between Pettenkofer's reaction and Gmelin's test? Describe each.
3. What is meant by diffusion and osmosis?
4. Describe the effect of strychnia on the central nervous system.
5. State what you know of the composition and physiologic action of the pancreatic secretion.
6. Through what three main channels is water lost from the body. Describe the function of each.

PATHOLOGY.

1. Describe the various laboratory methods of sterilization and explain the meaning of the term "fractional sterilization."
2. Give Koch's dicta (laws) regarding the bacterial cause of disease and state whether these dicta (laws) are fulfilled in the following diseases: Typhoid fever; croupous pneumonia; diphtheria: measles.
3. Give Cohnheim theory regarding the cause of tumor formation. Define sarcoma and carcinoma and give the usual method of metastatic extension of each.
4. Describe the gross and microscopic appearances of a solitary gray or miliary tubercle. Give in detail the method of staining tubercle bacilli in the sputum.
5. Describe the autopsy findings, as regards the vascular and urinary systems, one would expect in a case of arteriosclerosis of long standing.
6. Describe what you consider the most characteristic anatomic lesion of typhoid fever and give the chief avenues of elimination of the specific organism from the body.

ANATOMY.

1. Describe the thoracic duct.
2. Name the muscles of the eye and give their nerve supply.
3. What are the ureters and where do they begin and end?
4. Name anatomic structures severed by a circular amputation through the middle of the forearm.
5. (a) What are the divisions of the brain? (b) Name ventricles of the brain. (c) What arteries supply the membranes of the brain?
6. After a ligation of the axillary artery in its middle third, how is collateral circulation established?

The Public Service

Army Changes.

Memorandum of changes of stations and duties of medical officers, U. S. Army, week ending September 23:

Allen, John H., asst.-surgeon relieved from duty at the Army General Hospital, Presidio of San Francisco, and ordered to Fort Sill, O. T., for duty.

Rich, Edwin W., asst.-surgeon, relieved from temporary duty at Depot of Recruits and Casuals, Fort McDowell, Cal., and from further duty in the United States transport service, and ordered to Fort Ontario, N. Y., for duty.

Dale, F. A., asst.-surgeon, leave of absence extended thirty days.

Williamson, L. P., asst.-surgeon, granted two months and ten days' leave of absence, with permission to go beyond the sea.

Truby, Albert E., asst.-surgeon, ordered to accompany 3d Battalion of Engineers from Presidio of San Francisco, to Fort Leavenworth, Kans., then return to his proper station.

Banister, Wm. B., surgeon, left Jefferson Barracks, Mo., on thirty days' leave of absence.

Reynolds, Chas. R., asst.-surgeon, granted leave of absence for one month and fifteen days.

Kennedy, James M., asst.-surgeon, leave of absence extended thirty days.

Cass, William E., contract surgeon, relieved from duty in the Philippines Division, and ordered to Vancouver Barracks, Wash., for duty.

Woods, Oscar W., contract surgeon, relieved from duty at Vancouver Barracks, Wash., and ordered to the Army General Hospital, Fort Bayard, N. M., for duty.

Wall, Francis M., contract surgeon, left Fort Fremont, S. C., and arrived at Fort Oglethorpe, Ga., for duty.

Halliday, Francis A., contract surgeon, arrived at Fort Fremont, S. C., for duty.

Carpenter, Alden, dental surgeon, ordered to Fort Liscum, Alaska, for temporary duty.

Gardner, Fletcher, contract surgeon, relieved from duty in the Philippines Division, and ordered at the expiration of his present leave of absence to Fort Crook, Neb., for duty.

Hereford, John R., contract surgeon, arrived at San Francisco, on leave of absence for three months, from the Philippines Division.

Boak, S. Davis, dental surgeon, ordered to Fort Washington, Md., for temporary duty, from Fort Myer, Va.

Treuholtz, Clarence A., contract surgeon, returned to duty at the Army General Hospital, Fort Bayard, N. M., from temporary duty in Alaska.

Suggs, Frank, contract surgeon, reported for duty at Fort Mansfield, R. I., after two months' sick leave of absence.

Ware, William H., dental surgeon, left Fort DuChesne, Utah, and arrived at Fort Douglas, Utah, for temporary duty.

Branch, Frederick D., contract surgeon, returned to duty at Fort Wood, N. Y., from sick leave of absence.

Navy Changes.

Changes in the Medical Corps, U. S. Navy, for the week ending September 23:

Thompson, J. C., Benton, F. L. surgeons, commissioned surgeons, with rank of lieutenant commander, from March 3, 1903.

Garton, W. M., surgeon, commissioned surgeon, with rank of lieutenant commander, from March 12, 1903.

McCullough, F. E., surgeon, commissioned surgeon, with rank of lieutenant commander, from June 9, 1903.

Furlong, F. M., surgeon, commissioned surgeon, with rank of lieutenant commander, from June 20, 1903.

De Valin, H., acting asst.-surgeon, resignation accepted, to take effect September 20.

Public Health and Marine-Hospital Service.

List of changes of station and duties of commissioned and non-commissioned officers of the Public Health and Marine-Hospital Service for the seven days ending September 20:

Banks, C. E., surgeon, to proceed from Flomaton, Ala., to Magnolia Bluff, Fla., for special temporary duty.

Stoner, J. B., surgeon, granted leave of absence for two days, from September 16.

Goldberger, Joseph, P. A. surgeon, to proceed from Mobile, Ala., to New Orleans, and report to P. A. surgeon N. J. Rosenau for special temporary duty.

Foster, A. D., asst.-surgeon, granted leave of absence for seven days, from August 7, 1905, under paragraph 191 of the regulations.

Peters, R. H., acting asst-surgeon, to proceed from Livingston, Guatemala, to Zacapa, Gualan, Las Amates and Puerto Barrios for special temporary duty.

Stearns, W. L., pharmacist, to proceed to Magnolia Bluff, Fla., and report to Surgeon Banks, for special temporary duty.

BOARDS CONVENED.

Board to meet at Bureau in Washington, D. C., on Monday, September 18, for the purpose of examining candidate for entrance as cadet in the Revenue Cutter Service. Detail for the Board: Asst.-Surgeon J. W. Trask, chairman; H. McG. Robertson, recorder.

Health Reports.

The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon General, Public Health and Marine-Hospital Service, during the week ended September 16, 1905:

SMALLPOX—UNITED STATES.

California: Los Angeles, Aug. 26-Sept. 2, 1 case; San Francisco, 2 cases.

District of Columbia: Washington, Aug. 26-Sept. 9, 9 cases.

Massachusetts: Lowell, Aug. 26-Sept. 2, 1 case.

Michigan: Grand Rapids, Aug. 26-Sept. 9, 1 case, 1 death.

New York: New York, Aug. 26 Sept. 2, 1 case.

SMALLPOX—FOREIGN.

Africa: Cape Town, July 22-29, 7 cases.

Brazil: Bahia, Aug. 6-12, 3 deaths; Rio de Janeiro, July 27-Aug. 6, 23 cases, 5 deaths; Aug. 13-20, 9 cases, 7 deaths.

Cuba: Santiago Province, Aug. 29-Sept. 5, 2 cases, 1 death.

Ecuador: Guayaquil, Aug. 1-8, 4 deaths; Aug. 15-22, 1 death.

France: Paris, Aug. 19-26, 17 cases, 9 deaths.

Great Britain: Newcastle-on-Tyne, Aug. 16-23, 1 case.

India: Calcutta, July 29-Aug. 5, 3 deaths; Madras, July 29, Aug. 4, 6 cases.

Mexico: City of Mexico, Aug. 12-26, 15 cases, 9 deaths.

Russia: St. Petersburg, Aug. 6-19, 7 cases.

Turkey: Constantinople, Aug. 6-20, 7 deaths.

YELLOW FEVER—UNITED STATES.

Florida: Pensacola, Aug. 29-Sept. 12, 38 cases, 6 deaths.

Louisiana: Ascension Parish, to Sept. 10, 44 cases, 3 deaths; Assumption Parish, Aug. 26-Sept. 11, 13 cases; Caddo Parish, to Sept. 9, 4 cases, 1 death; East Baton Rouge Parish, Sept. 9, 1 case; East Carroll Parish, Aug. 14-Sept. 12, 106 cases, 9 deaths; Iberville Parish, to Sept. 11, 14 cases, 6 deaths; Jefferson Parish, 215 cases, 27 deaths; Lafayette Parish, to Sept. 12, 7 cases; Lafourche Parish, to Sept. 10, 332 cases, 35 deaths; Madison Parish, Aug. 14 Sept. 10, 87 cases, 12 deaths; Orleans Parish, New Orleans, July 21-Sept. 13, 2,406 cases, 323 deaths; Plaquemines Parish, to Sept. 11, 54 cases, 7 deaths; Rapides Parish, to Sept. 3, 7 cases; St. Bernard Parish, to Sept. 12, 33 cases, 1 death; St. Charles Parish, to Sept. 12, 94 cases, 16 deaths; St. James Parish, to Sept. 9, 6 cases; St. John the Baptist Parish, to Sept. 11, 149 cases, 14 deaths; St. Mary Parish, 478 cases, 18 deaths; St. Tammany Parish, 2 cases, 1 death; Terrebonne Parish, to Sept. 9, 90 cases, 3 deaths.

Mississippi: Anguilla, vicinity of Sept. 6, 1 case, imported; Gulfport, Aug. 15-Sept. 11, 53 cases; Gulf Quarantine, July 22-Aug. 26, 57 cases, 1 death; Mississippi City, Aug. 22-Sept. 11, 40 cases; Natchez, to Sept. 11, 23 cases.

YELLOW FEVER—FOREIGN.

Brazil: Rio de Janeiro, July 30-Aug. 6, 7 cases, 3 deaths; Rio de Janeiro, Aug. 13-21, 3 cases, 2 deaths.

Ecuador: Guayaquil, Aug. 1-8, 1 death; Aug. 15-22, 1 death.

Guatemala: Gualon, Aug. 19-26, present.

Honduras: Puerto Cortez, Aug. 18-25, 2 deaths.

Mexico: Tehuantepec, Aug. 27-Sept. 2, 1 case; Tezonapa, 2 cases; Vera Cruz, 4 cases, 1 death.

Panama: Bocas Del Toro: Aug. 18-25, 1 case; Colon, Aug. 19-26, 2 cases; Panama, 5 cases, 2 deaths.

PLAGUE—FOREIGN.

Africa, Port Elizabeth, July 29-Aug. 5, 1 case.

Brazil: Rio de Janeiro, July 30-Aug. 6, 8 cases, 2 deaths; Aug. 13-20, 2 cases.

India: General, July 15-27, 2,578 cases, 1,810 deaths; Calcutta, July 29-Aug. 5, 14 deaths.

Panama: La Boca, Aug. 6, 1 death.

CHOLERA—FOREIGN.

India: Calcutta, July 29-Aug. 5, 15 deaths; Madras, July 29, Aug. 4, 6 deaths.

Japan: Kobe, July 29-Aug. 12, 2 cases.

Medical Organization

California.

Monterey County Medical Society.—At a meeting of this society August 5, in Monterey, it was decided by unanimous vote to incorporate the society.

Solano County Medical Society.—A number of physicians of the county met at Vallejo, July 28, and organized a county medical society to be in affiliation with the state society and the American Medical Association. The following officers were elected: Dr. H. O. Miller, Vallejo, president; Dr. G. C. Browne, Benicia and Samuel G. Bransford, Suison, vice-presidents; Dr. Chadwick E. Arnold, Vallejo, secretary; Dr. Bernard J. Klotz, Vallejo, treasurer, and Drs. Lester P. Hall, Dixon; Winfield S. Makemson, Rio Vista; and W. L. McFarland, Benicia, censors.

Indiana.

Carroll County Medical Society.—This society met at Camden August 18 and reorganized with the following officers: President, Dr. Wilber F. Sharrer, Delphi; vice-president, Dr. Judson J. Schultz, Delphi; secretary, Dr. Charles C. Crampton, Delphi, and treasurer, Dr. Patrick W. Conway, Ockley.

Pennsylvania.

Fifteenth District Medical Association.—Physicians of Blair, Cambria, Clearfield and Center counties met at Lakemont Park, Altoona, August 15, and organized a district association, electing Dr. Frank A. Ford, Altoona, president, and Dr. James L. Henderson, Osceola Mills, secretary.

West Virginia.

Jefferson County Medical Society.—Physicians of Charlestown and Jefferson County met at Charlestown August 18, to reorganize a county medical association. Dr. J. J. Pittman, Charlestown, presided, and Dr. George A. Davis, Summit Point, acted as secretary. A letter from the secretary of the West Virginia Medical Association, outlining a plan for reorganization was read, after which the meeting adjourned to meet in Shepardstown, September 1, to complete organization.

Society Proceedings

COMING MEETINGS.

Colorado State Medical Society, Colorado Springs, October 3-5.

American Association of Railway Surgeons, Chicago, October 4-6.

Idaho State Medical Society, Boise, October 5-6.

Delaware State Medical Society, Wilmington, October 10.

Mississippi Valley Medical Association, Indianapolis, October 10-12.

Vermont State Medical Society, Burlington, October 12-13.

New York State Medical Association, New York City, October 16-19.

Kentucky State Medical Association, Louisville,, Oct. 5.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Eighteenth Annual Meeting, held at New York, Sept. 19-21, 1905.

The President, Dr. Howard W. Longyear, in the Chair.

The association met in College Hall of Hotel Astor, and, after an address of welcome by Dr. George B. Fowler, New York, which was responded to by Dr. Charles A. L. Reed, Cincinnati, proceeded with the reading of papers.

Annual Dinner.

The annual dinner was held at the Hotel Astor, September 20. The toastmaster was Dr. Robert T. Morris. The following toasts were responded to: "American Medical Association," Dr. L. S. McMurtry; "Our Nippon Neighbors," Surgeon-General Suzuki, Imperial Japanese Navy; "American Gynecological Society," Dr. Hermann J. Boldt; "The Doctor's Vacation," Dr. Brooks H. Wells; "In Manchuria with the Belligerents," Dr. L. L. Seaman; "Problems of Public Health," Dr. Daniel Lewis.

Officers.

The following officers were elected: President, Dr. John Young Brown, St. Louis; vice-presidents, Drs. James N. West, New York, and Frank F. Simpson, Pittsburg, Pa.; secretary, Dr. William Warren Potter, Buffalo, N. Y. (re-elected); treasurer, Dr. X. O. Werder, Pittsburg, Pa. (re-elected); members of council, Drs. Robert T. Morris, New York, and Howard W. Longyear, Detroit.

Multiple Pregnancy Complicated by Double Pyosalpinx.

Dr. O. H. Elbrecht, St. Louis, reported an interesting case in detail. The most striking feature was the obscurity of this fortunately rare complication, for without the autopsy he would certainly have abided by his first and only antemortem diagnosis, i. e., sapremia, and would have continued to believe that the general peritonitis was the result of the sapremic infection traveling upward through the tubes and thus into the abdominal cavity, for such a process, to his mind, would be all the more plausible in the large and flabby uterus of multiple pregnancy, more especially from the fact that large blood clots were passed on the first day, showing the relatively imperfect contraction of the uterus. The case also shows very plainly the ability or the degree of tolerance of the pelvic peritoneum to cope with infections, as it is his opinion that the peritonitis was not general until the sixth day, for up to that time there was no hiccoughing, no vomiting, no abdominal distension and no apparent weakness. Another deduction is that gonorrheal peritonitis, while not very dangerous, if confined to the pelvic peritoneum, is surely dangerous when it creeps out of the pelvis and becomes diffuse. It is also his firm belief that the pyosalpinx in this case was unilateral at the time of impregnation, and that the infection was transmitted by the escape of virulent pus to the open fimbriæ of the unaffected side.

The only cases he could find analogous to his have been reported by Hare and Talley. The reports of two pathologists in the speaker's case, who worked independently of each other, both showed that the tube, which was secondarily infected, was infected by way of the fimbriæ, as its pathology was confined entirely to its outer third; the middle third showed only slight inflammatory changes, and the inner third, including the uterine attachment, was normal.

Blank projects the theory that virulent bacteria in the tube have a tendency to become pyosalpinx during pregnancy by reason of the hyperemia. He further states that 50 per cent. of those cases in which the tubes are adherent in the cul-de-sac rupture as pregnancy advances, from tension, pressure or from stretching of the adhesions, which forces pus out of their fimbriated extremity. The experience of the essayist with three cases of this class substantiates Blank's theory. These three cases were reported.

DISCUSSION.

Dr. Charles A. L. Reed, Cincinnati, said that this case, with the pus tube undetachable, only adds one possible condition that points to the reason why possibly these cases should be subjected to operation earlier and more radically than they have been heretofore. With a double pus tube, with antecedent conception, it follows that the deduction of the essayist, that the infection of the tube was unilateral prior to impregnation, was absolutely incontrovertible. As to infection on the other side, the probability is that it resulted from a progressive invasion of tissue, the mucous structure serving as a nidus of infection occurring within the uterus following delivery.

Dr. Herman E. Hayd, Buffalo, N. Y., is inclined to believe that we see many cases of pyosalpinx complicating delivery that are due to a latent gonorrhea existing in the tube, which springs into activity as a result of the trauma incident to labor.

Dr. Charles L. Bonifield, Cincinnati, believes many cases of double pyosalpinx clear up sufficiently to allow the patients to become pregnant. In years gone by he told patients they would never become pregnant when he detected a mass on each side and there were further evidences of pyosalpinx, and on a few occasions he has been deceived after six, eight or twelve years, the pus having become absorbed and the women having become pregnant. He cited a case he had many years ago of double pyosalpinx, or he thought it was such. The woman refused operation. Everything in the pelvis was matted together. She gradually got better, and at the end of six or eight years became pregnant, and he delivered her. She passed through labor nicely, but at the end of a week she suddenly raised herself in bed and dropped over dead.

Dr. Rufus B. Hall, Cincinnati, does not believe that a woman with double pus tubes can afterward become pregnant. If such a woman should become pregnant he would be inclined to doubt the diagnosis of bilateral pyosalpinx.

Dr. John Young Brown, St. Louis, thinks the mere existence of pregnancy in the case narrated by the essayist precludes the possibility of the woman having had bilateral pyosalpinx. The pathology, as revealed by the autopsy, shows conclusively that the case was one of unilateral pyosalpinx, which was dormant and lighted up by the trauma of labor, and that the leakage from the pus tube produced the diffuse peritonitis, and the condition found on the other side was due to bathing this side with the pus that was produced by the peritonitis.

Dr. James F. Baldwin, Columbus, Ohio, has not had a case of double pyosalpinx followed by pregnancy, yet he thinks it may occur.

Dr. Lewis S. McMurtry, Louisville, Ky., said abdominal section in a puerperal convalescent is a very serious procedure. The operation of vaginal incision and drainage, so enthusiastically advocated by Pryor, would accomplish very little in a case like the one reported from the standpoint of therapeutics; hence, in the case reported we have a very valuable addition to the scanty literature of the subject as to the possibility of pathology of the tubes connected with puerperal disease, and a valuable guide to operative interference.

Some General Principles in Conservative Pelvic Surgery.

Dr. John F. W. Whitbeck, Rochester, N. Y., said that it is decidedly advantageous to have a general knowledge and a general experience before making use of special methods in the treatment of pelvic disorders. Medical and mechanical means should be tried in suitable cases before resorting to surgical intervention. Only diseased organs should be removed. Sound organs and normal parts of unhealthy organs should be preserved. Conservative plastic surgery should be employed to save such organs as can be made functional or to serve some useful purpose. Diseased organs should be removed in the order of their pathologic precedence and importance, with a view to benefit the patient by promoting her comfort and prolonging her life, even if a perfect cure is not to be expected.

Cesarean Section.

Dr. Henry Schwarz, St. Louis, reported the case of a child wife who was in labor sixty hours, with repeated attempts at forceps delivery by the family physician. Apparently she was not infected. Instead of a Porro, as is usual in such cases, he did the classical Cesarean operation, which was followed by recovery of both mother and child. The baby was asphyxiated, membranes and amniotic fluid yellowish green. His assistant worked over the baby an hour at artificial respiration before spontaneous breathing was established. Pressure marks on the scalp showed locking of the head between the promontory and symphysis; necrotic tissue dropped out a few days afterward, and the baby recovered.

Pregnancy Associated with Diabetes.

Dr. Magnus A. Tate, Cincinnati, mentioned the reports of numerous investigators, calling attention to sugar in the urine of pregnant women. He collected all cases that could be found in medical literature where pregnancy was complicated by diabetes. He reported an additional case, and presented a study of these tabulated cases as to their frequency, results, mortality and other similar data.

Cysts of the Mesentery.

Dr. Orange G. Pfaff, Indianapolis, said that these growths are comparatively rare; their diagnosis is difficult, if not impossible; their pathology is not fully and clearly understood, but most of them, if not all, are of probable embryonal origin. He reported two exceedingly interesting and instructive cases.

(*To be continued.*)

AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARNYGOLOGY.

Tenth Annual Meeting, held at Buffalo, N. Y., Sept. 14-16, 1905.

(*Continued from page 939.*)

The Lens Capsule in the Operation of Cataract.

Dr. Herman Knapp, New York, said that if one lives long enough he will get cataract. He has never seen a patient who, after having attained the age of say 80, did not have a cataract. Only a very small proportion, however, of these cases come to operation. The capsule is the most unpleasant feature in cataract operations, and should be removed with the cataract. Since he has been doing flap extraction he has not had a case of sympathetic ophthalmia. He described his own technic of the operation, and referred to some of the accidents and complications met with in cataract extraction.

Accidents and Complications in Cataract Extraction.

Dr. D. W. Greene, Dayton, Ohio, gave a brief review of the history of the operation, showing the evolution through which the different stages have passed from Petit (1706), Daviel (1745), to the present time. The shifting of the section forward is now accomplished until it is now made entirely corneal. He referred to the smaller iridectomy or its entire omission, and described the different methods of opening the capsule and delivering the lens and cortical débris. Reference was made to the so-called toilet of the operation. He said the combined operation is usually made. He spoke of the accidents in and what are complications of the operation. A strict definition of each is difficult. He outlined the management of a normal case, also the management of accidents and complications. Accidents are usually operative. Complications may be present at the time of operation; they may result from accidents during operation, but as a rule are postoperative. Age as such is never a contraindication. The physical and mental conditions incident to it may be complications. He discussed the matter of when the lens is extracted within the capsule. Allusion was made to the use of flannel bandages, lint and cotton compresses in the treatment. Confinement in bed is not rigidly enforced after the second day. All of the things mentioned are intended to lead up to and make clear the title of the paper, as well as the subjects treated under it.

DISCUSSION.

Dr. John E. Weeks, New York, said that in operating for cataract the incision should be made in the vascular portions of the eye, that is, at the limbus, making a conjunctival flap. He now makes a conjunctival flap in all cases. He removes a portion of the capsule. The method of opening the capsule advocated by Knapp is a good one, but is not free from objection. The method recommended by von Graefe for opening the capsule is excellent. He prefers the combined operation rather than simple extraction.

Dr. Edward Jackson, Denver, has for several years practiced opening the capsule; he demonstrated his method of doing it.

Dr. Alvin A. Hubbell, Buffalo, said the incision of Daviel is ideal, but Dr. Hubbell makes it upward instead of downward, almost at the corneo-scleral junction. The drawbacks of the simple operation are greatly in excess of those of the combined method. He prefers the combined operation. The capsule can be opened centrally. He favors the T-shaped incision of von Graefe, and spoke of the importance of irrigating the anterior chamber.

Dr. Eugene Smith, Detroit, said that it is an easy matter to remove the anterior capsule in operating for cataract, and he has been doing this for several years—fifteen or twenty years. He prefers simple extraction in suitable cases, the combined operation in others. He advocates the use of capsule forceps.

Dr. Baker, Cleveland, added his testimony to the value of the peripheral capsulotomy of Knapp. He favors the combined method.

Dr. J. E. Willis, Pittsburg, said the lens should be extracted as soon as possible, and with the least interference with the eye. He favors simple extraction, as he gets better results. He thinks it is an ideal operation. He believes a preliminary iridectomy is unnecessary.

Cyst of the Thyroglossus Duct.

Dr. John J. Kyle, Indianapolis, stated that the thyroglossus duct is an embryologic structure which disappears about the eighth week of fetal life. From faulty growth the duct may remain and manifest itself in extrauterine life by the formation of a cyst, which may be situated near the base of the tongue or between the deep fauces of the neck, and between the hyoid bone and the thyroid cartilage. The review of the literature was given with the description of the case observed in a woman 45 years of age.

DISCUSSION.

Dr. Andrew Timberman, Columbus, has never seen a case of cyst of the thyroglossus duct. He spoke of the difficulties attending the diagnosis of it.

Dr. Kate Wylie Baldwin, Philadelphia, has had two cases of cyst of the thyroglossus duct, one in a girl of 16 and the other in a woman of 25. In one the cyst was the size of a hickory nut; in the other the size of a pullet's egg. These cysts were thoroughly dissected out; healing by first intention occurred, and there has been no return.

Dr. Joseph C. Beck, Chicago, saw a case in the practice of Nicholas Senn, which was operated on, but in which recurrence took place.

The Pinguecula and Pterygium.

Dr. Adolph Alt, St. Louis, read a paper with this title which was illustrated by stereopticon slides. He reviewed the literature on this subject, with special reference to the connection between the two affections from the standpoint of the pathologist, and said that it rehabilitates in some measure Arlt's marginal ulcer as a cause of pterygium.

The Mammalian Eye.

Dr. Casey A. Wood, Chicago, gave a talk on the mammalian eye, illustrated by colored slides prepared from original drawings by the artist, Dr. A. W. Head. This is the first time these fundus pictures were ever presented or exhibited in America, and it is through the courtesy of Dr. Head that they were obtained.

Filaria Loa.

Dr. Derrick T. Vail, Cincinnati, discussed the varieties of nematodes simulating *Filaria loa* (eye worms); he described the parasite, its habitat, and mentioned the theories as to its development. He also spoke of the mode of infection and of the rarity of actual cases in this country. He reported a genuine case and exhibited specimens.

The Ciliary Processes in Accommodation.

Dr. F. Parke Lewis, Buffalo, spoke of the importance of accommodation in relation to the eye itself, and pointed out the difficulty of studying the problem from a physiologic standpoint. He said that pathology interrupts its smooth working and makes evident points otherwise obscure. Tension was directed to the inadequacy of the Helmholtz theory. The Tscherning's theory is more satisfactory, but is not explained by the mechanism. The relations and nature of the ciliary processes were discussed. Nature adapts an organism to existing necessities, but does not often vary fundamental principles. He describes the ciliary processes in the pig, in the reptile, in the bird, in the fish and in man, illustrated by a series of stereopticon slides. The segmental action of the ciliary processes is necessary to explain visual correction of an astigmatic cornea. There is conjugate action of corresponding segments in one eye or in both. He spoke of its importance in nutritive conditions of the lens, and in sympathetic ophthalmia in correlated brain centers.

Should Tonsillar Tissue Be Removed in All Cases?

DR. GEORGE W. SPOHN, Elkhart, Ind., said that the glandular tissue in the pharyngeal vault, between the pillars of the fauces, at the base of the tongue, within the ventricle of the larynx and within the nasal orifices, is generally known as the tonsillar tissue. As regional glands they are physiologic. As tonsils they should be known as pathologic conditions. As diseased glands, tonsils should be removed. When not diseased and normally functionating they should not be removed.

Spontaneous Hemorrhage into the Vitreous.

DR. THEODORE B. SCHNEIDEMAN, Philadelphia, stated that hemorrhages into the vitreous of traumatic origin are not very rare, but spontaneous hemorrhage is quite uncommon. The latter is dependent on changes in the walls of the blood vessels. Of constitutional affections responsible for such changes, tuberculosis, pernicious anemia, syphilis, malaria, are to be particularly mentioned. In older subjects atheroma occupies the first place. In the two cases the author reported the underlying cause was obscure. One occurred in a young man of 21, and the other in a neurotic woman about the time of the menopause.

Hemorrhage from the Eye.

DR. ALVIN A. HUBBELL, Buffalo, reported two cases of profuse hemorrhage from the eye. One was from the conjunctiva of a new-born infant after several instillations of a 2 per cent. solution of nitrate of silver, and the other from the eyeball of an adult whose cornea had become ulcerated and perforated in the course of a long-continued glaucoma.

DISCUSSION.

DR. W. L. DAYTON, Lincoln, Neb., mentioned a case of retinitis albuminurica occurring in a young patient in whom there was extensive hemorrhage into the vitreous about the macular region. The peripheral portion of the retina could be distinctly seen.

DR. F. PARK LEWIS thinks the cause of hemorrhage into the vitreous in some cases may be due, first, to some local degenerative condition of the vessels, and, second, to some irritative condition of sufficient intensity to cause the normal vessel to contract.

DR. PERCY FRIDENBERG, New York, narrated an interesting case of intraocular hemorrhage in connection with disorders of menstruation. In this case both retinæ became detached.

DR. EDWARD J. BERNSTEIN, Kalamazoo, Mich., reported a case of intraocular hemorrhages with fibrous bands in a boy of 14. The case progressed to complete disorganization of the eye.

DR. ALVIN A. HUBBELL recalled four cases of recurrent hemorrhages into the vitreous. All of the patients were males. Two were young men of 22 or 23. The other two were men in middle-life. In each case the hemorrhages occurred at irregular intervals, and the hemorrhages would absorb with very little destruction of vision. He has never seen a case of recurrent hemorrhage into the vitreous in a female. He has no explanation to offer as to the cause of these hemorrhages.

DR. GEORGE M. GOULD, Philadelphia, referred to eye-strain as a possible cause of hemorrhage into the vitreous. He has seen several cases of hemorrhage into the vitreous or anterior portions of the eye which he has relieved, and these were found to be due to eye-strain.

DR. H. B. YOUNG, Burlington, Iowa, has seen, in the past month, a case of spontaneous hemorrhage into the vitreous in a man, 30 years of age, married, of good habits, but who for years has had chronic albuminuria. Young considers the connection between a vitreous hemorrhage and albuminuria a definite one. He has also seen a case of excessive subconjunctival hemorrhage in a man of 50 without any known cause.

DR. L. A. W. ALLEMAN, Brooklyn, reported cases similar to those narrated by Gould.

DR. GOULD raised the point as to whether strong solutions of nitrate of silver may not cause these vitreous hemorrhages in some cases.

DR. ADOLPH ALT, St. Louis, mentioned a case in which one drop of a 2 per cent. solution of nitrate of silver was dropped on the cornea, and in a few hours thereafter hemorrhage from the conjunctiva occurred which could not be controlled, so that the child died in a week or less from exhaustion and exsanguination.

DR. JOHN E. WEEKS said that in the preparations of silver we have protargol and argyrol, which are efficient and harmless remedies. If argyrol is used in a strength of 35 per cent. solution, or protargol in a relatively strong per cent., the danger to the patient would be *nil*, and the effect produced would be as good, in his opinion, as that to be obtained by the use of nitrate of silver.

(To be continued.)

Therapeutics

[It is the aim of this department to aid the general practitioner by giving practical prescriptions and, in brief, methods of treatment for the diseases seen especially in every-day practice. Proper inquiries concerning general formulae and outlines of treatment are answered in these columns.]

Hyperidrosis.

Brocq, in *Archives de Méd. et Chir.*, recommends that insoles made of filter paper, linen or cork be saturated with the following mixture and allowed to dry before being inserted in the shoes:

℞.	Potas. perman	gr. xv	1
	Thymol	gr. viii	50
	Aquæ	℥iiiss	105

M. Sig.: Saturate the insoles with the solution, and after they have dried insert them into the shoes, and change daily. Or:

℞.	Naphthol	gr. lxxv	5
	Glycerini	ʒiiss	10
	Alcoholis	℥iiiss	105

M. Ft. lotio. Sig.: Bathe the feet well with the lotion and dust them with the following powder:

℞.	Naphthol	gr. xv	1
	Pulv. amyli	℥ii	60

M. Sig.: To be used as a dusting powder for the feet. Or the following powder may be used:

℞.	Pulv. talci	℥i	30
	Bismuthi subnit	ʒx	40
	Potass. perman	gr. xlv	3
	Sodii salicylatis	gr. xxx	2
	Pulv. amylii	℥ii	60

M. Ft. pulvis. Sig.: To be used locally as a dusting powder. Or:

℞.	Tinct. ferri chloridi	℥i	30
	Glycerini	ʒiiss	10

M. Ft. solutio. Sig.: Apply locally to the soles of the feet. Or:

℞.	Quin. sulphatis	gr. lxxv	5
	Acidi tonnici	gr. xxx	2
	Alcoholis	℥iii	90
	Aquæ	℥viii	240

M. Ft. lotio. Sig.: To be used as a wash for the feet. This is to be followed by a powder composed of:

℞.	Acidi salicylici	gr. xlv	3
	Pulv. amyli	ʒiiss	10
	Pulv. talci	℥iii	90
	Pulv. aluminis	℥iss	45

M. Ft. pulvis. Sig.: To be used as a dusting powder for the feet. Or:

℞.	Tinct belladonnæ	ʒvi	24
	Spiritus odoratus	℥iv	120

M. Sig.: To be applied locally to the sweating feet.

Treatment of Phlebitis.

Phlebitis, according to Robin in *Med. Press*, should be divided into three distinct phases: acute, convalescent and chronic.

betes. He reported an additional case, and presented a study of these tabulated cases as to their frequency, results, mortality and other similar data.

Cysts of the Mesentery.

Dr. Orange G. Pfaff, Indianapolis, said that these growths are comparatively rare; their diagnosis is difficult, if not impossible; their pathology is not fully and clearly understood, but most of them, if not all, are of probable embryonal origin. He reported two exceedingly interesting and instructive cases.

AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARNYGOLOGY.

Tenth Annual Meeting, held at Buffalo, N. Y., Sept. 14-16, 1905.

(Continued from page 939.)

The Lens Capsule in the Operation of Cataract.

Dr. Herman Knapp, New York, said that if one lives long enough he will get cataract. He has never seen a patient who, after having attained the age of say 80, did not have a cataract. Only a very small proportion, however, of these cases come to operation. The capsule is the most unpleasant feature in cataract operations, and should be removed with the cataract. Since he has been doing flap extraction he has not had a case of sympathetic ophthalmia. He described his own technic of the operation, and referred to some of the accidents and complications met with in cataract extraction.

Accidents and Complications in Cataract Extraction.

Dr. D. W. Greene, Dayton, Ohio, gave a brief review of the history of the operation, showing the evolution through which the different stages have passed from Petit (1706), Daviel (1745), to the present time. The shifting of the section forward is now accomplished until it is now made entirely corneal. He referred to the smaller iridectomy or its entire omission, and described the different methods of opening the capsule and delivering the lens and cortical débris. Reference was made to the so-called toilet of the operation. He said the combined operation is usually made. He spoke of the accidents in and what are complications of the operation. A strict definition of each is difficult. He outlined the management of a normal case, also the management of accidents and complications. Accidents are usually operative. Complications may be present at the time of operation; they may result from accidents during operation, but as a rule are postoperative. Age as such is never a contraindication. The physical and mental conditions incident to it may be complications. He discussed the matter of when the lens is extracted within the capsule. Allusion was made to the use of flannel bandages, lint and cotton compresses in the treatment. Confinement in bed is not rigidly enforced after the second day. All of the things mentioned are intended to lead up to and make clear the title of the paper, as well as the subjects treated under it.

DISCUSSION.

Dr. John E. Weeks, New York, said that in operating for cataract the incision should be made in the vascular portions of the eye, that is, at the limbus, making a conjunctival flap. He now makes a conjunctival flap in all cases. He removes a portion of the capsule. The method of opening the capsule advocated by Knapp is a good one, but is not free from objection. The method recommended by von Graefe for opening the capsule is excellent. He prefers the combined operation rather than simple extraction.

Dr. Edward Jackson, Denver, has for several years practiced opening the capsule; he demonstrated his method of doing it.

Dr. Alvin A. Hubbell, Buffalo, said the incision of Daviel is ideal, but Dr. Hubbell makes it upward instead of downward, almost at the corneo-scleral junction. The drawbacks of the simple operation are greatly in excess of those of the combined method. He prefers the combined operation. The capsule can be opened centrally. He favors the T-shaped incision of von Graefe, and spoke of the importance of irrigating the anterior chamber.

Dr. Eugene Smith, Detroit, said that it is an easy matter to remove the anterior capsule in operating for cataract, and he has been doing this for several years—fifteen or twenty years. (*To be continued.*)

Therapeutics

[It is the aim of this department to aid the general practitioner by giving practical prescriptions and, in brief, methods of treatment for the diseases seen especially in every-day practice. Proper inquiries concerning general formulae and outlines of treatment are answered in these columns.]

Hyperidrosis.

Brocq, in *Archives de Méd. et Chir.*, recommends that insoles made of filter paper, linen or cork be saturated with the following mixture and allowed to dry before being inserted in the shoes:

℞.	Potas. perman.	gr. xv	1	
	Thymol	gr. viii		50
	Aquæ	℥iiiss	105	

M. Sig.: Saturate the insoles with the solution, and after they have dried insert them into the shoes, and change daily. Or:

℞.	Naphthol	gr. lxxv	5
	Glycerini	ʒiiss	10
	Alcoholis	℥iiiss	105

M. Ft. lotio. Sig.: Bathe the feet well with the lotion and dust them with the following powder:

℞.	Naphthol	gr. xv	1
	Pulv. amyli	℥ii	60

M. Sig.: To be used as a dusting powder for the feet.

Or the following powder may be used:

℞.	Pulv. talci	℥i	30
	Bismuthi subnit.	ʒx	40
	Potass. perman.	gr. xlv	3
	Sodii salicylatis	gr. xxx	2
	Pulv. amylii	℥ii	60

M. Ft. pulvis. Sig.: To be used locally as a dusting powder. Or:

℞.	Tinct. ferri chloridi	℥i	30
	Glycerini	ʒiiss	10

M. Ft. solutio. Sig.: Apply locally to the soles of the feet. Or:

℞.	Quin. sulphatis	gr. lxxv	5
	Acidi tonnici	gr. xxx	2
	Alcoholis	℥iii	90
	Aquæ	℥viii	240

M. Ft. lotio. Sig.: To be used as a wash for the feet.

This is to be followed by a powder composed of:

℞.	Acidi salicylici	gr. xlv	3
	Pulv. amyli	ʒiiss	10
	Pulv. talci	℥iii	90
	Pulv. aluminis	℥iss	45

M. Ft. pulvis. Sig.: To be used as a dusting powder for the feet. Or:

℞.	Tinct belladonnæ	ʒvi	24
	Spiritus odoratus	℥iv	120

M. Sig.: To be applied locally to the sweating feet.

Treatment of Phlebitis.

Phlebitis, according to Robin in *Med. Press*, should be divided into three distinct phases: acute, convalescent and chronic.

As soon as the trouble is properly diagnosed the limb should be placed in a box or wire splint and well covered with cotton wool, first powdering it with the following:

℞.	Acidi boracici	ʒiii	12
	Pulv. talci	℥iii	90

M. Ft. pulvis. Sig.: Dust over the affected limb before applying the splint.

He does not recommend the local application of ointments as usually recommended during this stage, but prefers the dry treatment. Milk should be the principal article of diet. At the end of three weeks or a month the second stage, as mentioned by the author, begins, when the splint should be removed from the limb and the limb gently rubbed with a lubricant such as lanolin or oil of theobroma, and again enveloped in cotton wool and allowed to rest on a support for three days. If at the end of that time no pain is felt or any rise of temperature observed, the covering may be removed and the following gently applied locally once a day:

℞.	Ext. hamamelidis flu	ʒss	2
	Lanolini	℥i	30

M. Ft. unguentum. Sig.: Apply locally to the affected limb.

At this period the limb may be given massage in a gentle manner to promote the general circulation. It must be done lightly with the palm of the hand for five or six minutes once a day. In order to facilitate resolution the following may be rubbed in every evening:

℞.	Ergotin	ʒi	4
	Kalii iodidi		
	Ext. nucis vom., āā	ʒss	2
	Lanolini	℥i	30

M. Ft. unguentum. Sig.: Apply locally.

After fifteen days of this treatment active and passive movements of the limb are recommended by the author, these consisting in flexion, extension, abduction and rotation of the foot.

The treatment of phlebitis is concluded by the author by applying a bran bath every day for twenty minutes, gradually lengthening the time to forty-five minutes. After the bath the patient must be instructed to rest for half an hour, when massage should be given for ten minutes, followed by a rest of thirty minutes, when the patient may be allowed to take a little exercise on the feet. This treatment may be kept up for three weeks, but the author cautions against giving massage in the region of the large veins, in the popliteal space, in Hunter's canal or in Scarpa's triangle. To promote the nutrition of the atrophied muscles and to improve the venous circulation walking is recommended in moderation, avoiding fatigue. This author forbids the patient standing or sitting down; he must either walk or lie down.

To Prevent the Shedding of Hair.

David Walsh of London, according to an abstract in *Med. Standard*, recommends the following combination to prevent the hair from falling out, stating that it is preferable to an ointment, especialy in the cases of women:

℞.	Acidi salicylici	ʒiii	12
	Acidi carbolici	ʒi	4
	Olei ricini	ʒiii	12
	Spts. vini rectif. q. s. ad	℥vi	180

M. Sig.: Apply locally once or twice daily.

Mucus Colitis.

R. C. Kemp, in *Amer. Med.*, recommends in the treatment of mucus colitis that the patient be put to bed and heat applied to the abdomen by means of flaxseed poultices, turpentine stupes or hot pepper poultices, using dram one (4.00) of red pepper to a pint of boiling water, a flannel wrung out of this solution applied to the abdomen and covered with oiled silk. Dry heat may be employed if necessary by means of a hot-water bag, a hot bag of salt or a tin plate heated and covered by flannel and applied to the abdomen. Moist heat, however, is preferable. The greatest relief from the cramp, according to the author, are afforded by enteroclysis, using a recurrent irrigator and the normal saline solution at a temperature of from 110 to 120 F., and adding the oil of peppermint, from five (.30) to fifteen minims (1.00) to the quart of water. Several gallons may be used once or twice in the twenty-four hours, allowing no water to remain in the bowels to excite further cramps. High enemas of olive oil, using a pint or a quart of the oil, are also of value in relieving the spasm in similar manner to the relief of spasm of the pylorus by the internal administration of olive oil.

Hot saline enemas containing from two to four ounces (60 to 120) of the milk of asafetida are also of value in relieving the cramps.

Liquid diet, such as broths, soups and milk, should be prescribed. The *tincture of belladonna* as recommended by all authors is advised, beginning with 10 minim doses every three or four hours, and increasing the dose till the physiologic symptoms occur, is recommended to give relief from the spasms. Occasionally the author resorts to codein in doses of grain 1/4 to grain 1/2 (.015 to .03), or even morphin in doses of grain 1/8 to grain 1/4 (.008 to .015) when the pain is excessive.

If the acute attack is prolonged the valerianates or asafetida are recommended internally and the milk of asafetida as an enema. Between the attacks proper support to the abdomen is advised, producing pressure backward and upward by means of a silk abdominal supporter, or in its stead an adhesive plaster belt. If the latter is used the surface of the abdomen must be smoothly shaven and cleansed with alcohol or ether before the adhesive belt is applied. The belt should be changed about once in four weeks. To relieve constipation enemas of the normal saline solution are recommended several times a week to promote intestinal peristalsis, and in this way to prevent the accumulation of mucus and thus to lessen the tendency to the recurrence of the spasms. He emphasizes the importance of using only the normal saline solutions or the demulcents as enemas for the removal of the mucus, as the condition is due to hypersecretion and not to inflammation. He avoids the use of irrigations of silver, tannin, alum, etc., as they can produce an artificial hypersecretion. Nux vomica or strychnia may be given between the attacks to increase the muscular tone of the intestine. If much gastrointestinal fermentation is present the following combination is recommended:

℞.	Resorcini	gr. v	30
	Sodii benzoatis		
	Bismuthi salicylatis, āā	gr. v-x	30-.65

M. Ft. capsula No. i. Sig.: One such capsule three times a day before food.

W. H. Thomson recommends the following in mixed cases in which some catarrh of the intestine is present:

℞.	Argenti nitratis	gr. v	30
	Resinæ terebinthinæ	ʒiii	12
	Liq. potassæ	ʒi	4
	Pulv. glycyrrhizæ q. s.		

M. Ft. pil. No. lx. Sig.: Three pills three times a day.

Copper sulphate grain 1/4 (.015) may be substituted for the foregoing later. Fowler's solution in one-drop (.06) doses three times a day is also recommended in mixed cases.

The general treatment consists in outdoor exercise, such as golf, to strengthen the abdominal muscles, and in winter fencing is of value. Anemia must be corrected by means of Bland's mass combined with small doses of arsenic and nux vomica.

Medicolegal

Age or Weight and Personal Injuries.—The Court of Errors and Appeals of New Jersey holds, in the personal injury case of Staines vs. Central Railroad Company of New Jersey, that the fact that the injuries of the plaintiff would not have happened to a younger person, or one of less weight, did not absolve the defendant from liability for such injuries.

Injured Physician May Testify as to Earnings.—The Supreme Court of Missouri says, in the case of Sluder vs. St. Louis Transit Co., where a physician was incapacitated to practice his profession for eleven and one-half weeks by a collision of a street car with a carriage in which he was riding, that no reason was stated why it was not competent for the physician himself to testify what his actual monthly practice averaged him. It was not guesswork, but actual knowledge, to which he was testifying. It was not remote, but the value of his profession to him for the immediate months during which he was disabled, and the court agrees with him that the best evidence was the actual earnings of the month in which he was injured. In other words, the court holds that there was no error in permitting him to testify to his earnings for the corresponding months of the previous year.

Mental Disease Relieving from Criminal Responsibility.—The Supreme Court of Georgia holds, in Allams vs. State, that where the accused on trial for murder relied on the defense of insanity at the time of the homicide, it was not error to instruct the jury that the burden was on him to show "that at the time of the killing he was not of sound memory and discretion. He must show this not beyond a reasonable doubt, but to the reasonable satisfaction of the jury, by a preponderance of the evidence." Nor was it error on the trial of such a case to charge the jury that, if the accused had been shown to be insane prior to the date of the homicide, the presumption would be that he continued to be insane, "and the burden of proof would be on the state to show to the reasonable satisfaction of the jury, by a preponderance of the evidence, that at the time of the alleged homicide the defendant was of sound memory and discretion."

The rule of law in force in Georgia which relieves one from criminal responsibility for the commission of an unlawful act on account of mental disease is: If a man has reason sufficient to distinguish between right and wrong in relation to a particular act about to be committed, he is criminally responsible. An exception to this rule is where a man has reason sufficient to distinguish between right and wrong as to a particular act about to be committed, yet, in consequence of some delusion, his will is overmastered, and there is no criminal intent, provided that the act itself is connected with the peculiar delusion under which the prisoner is laboring. It follows, therefore, that it was not accurate to charge as follows: "The insanity which the law recognizes as an excuse for crime must be such as dethrones reason and incapacitates an individual from distinguishing between right and wrong as to the particular act in question, and of being mentally incapable of choosing to do or not to do the alleged act, and governing his conduct in accordance therewith." To relieve one from criminal responsibility on account of mental delusion for the commission of an unlawful act, it is not necessary that he be incapable of distinguishing right from wrong as to the particular act in question, and also incapable of choosing to do or not to do such act, and of governing his conduct in accordance therewith.

Alcoholic Compounds Labeled as Medicines.—The United States Commissioner of Internal Revenue says, in Internal Revenue Circular No. 673, dated Sept. 12, 1905, addressed to collectors of internal revenue, with regard to alcoholic compounds labeled as medicines and held out to the public as remedies for diseases.

Among the various alcoholic compounds now on the market, advertised and sold under the name of whisky, bitters, tonic, cordials, etc., there are some that are composed chiefly of distilled spirits, or mixtures thereof, without the addition of drugs or medicinal ingredients in sufficient quantities to change materially the character of the alcoholic liquor.

The fact that these compounds during the existence of the statute imposing tax on proprietary medicines were without the necessity of investigation into their character by the terms of the law made subject to that tax, because they were held out to the public as medicines, does not afford ground for relieving the manufacturers from special tax as rectifiers and liquor dealers, or dealers therein from special tax as liquor dealers under the provisions of Section 3244, Revised Statutes, and amendments.

It is held that the statute requires the exaction of this special tax from the manufacturer of every compound of distilled spirits, even though drugs are declared to have been added thereto, when their presence is not discoverable by chemical analysis, or it is found that the quantity of drugs in the preparation is so small as to have no appreciable effect on the alcoholic liquor of which the compound is mainly or largely composed.

The same ruling applies to every alcoholic compound labeled as a remedy for diseases and containing, in addition to distilled spirits, only substances or ingredients which, however large their quantity, are not of a character to impart any medicinal quality to the compound; but where substances undoubtedly medicinal in their character are combined with whisky or other alcoholic liquor, and are used in sufficient quantity to give a medicinal quality to the liquor other than that which it may inherently possess, such compound is, of course, not to be included in this ruling.

The question, in each case, arising under the terms of this circular will be determined by this office, not merely on examination of the formula submitted by the manufacturer of the compound, but on result of the analysis in the chemical laboratory here of samples obtained in the open market and sent in by the local internal revenue officers and agents.

The ruling as to these compounds in the fourth paragraph of Circular No. 608 (Treasury Decisions, 1901, Vol. 4, p. 210), "that if they are composed of spirits in combination with drugs, herbs, roots, etc., and are held out as remedies for diseases stated in labels on the bottles, they are to be regarded as medicines until the facts ascertained, as to the purpose for which they are usually sold or used, show them to be beverages, and until such facts are obtained druggists and merchants who sell these compounds in good faith as medicines only are not to be called on to pay special tax as liquor dealers on account of such sales," is hereby revoked.

But in order that no injustice may be done to these druggists and merchants who, without holding special-tax stamps as liquor dealers, now have in stock these compounds for sale as medicines, this circular will not be put into effect until Dec. 1, 1905.

Collectors will, however, immediately on the receipt of this circular send out notice to all druggists and merchants dealing in proprietary medicines in their districts who do not hold the requisite special-tax stamp as liquor dealers, that on and after Dec. 1, 1905, they will be required to pay special tax for selling the alcoholic compounds coming within the ruling now promulgated, even when they sell them in good faith for medicinal use only, never selling them as beverages, nor selling them knowingly to those buying them for use as beverages. [In this connection, see editorials Sept. 23 and 30, 1905.]

2. Therapeutic Value of Bactericidal Serums.—Pease reviews some of the clinical results obtained by the use of the various antistreptococcic serums in streptococcus infections, scarlet fever, rheumatism and smallpox, and the antipneumococcic, antityphoid, antituberculosis, antidysenteric, antiplague and antianthrax serums in their respective diseases, and calls attention to the variability in the reports of different writers on their results from the use of these serums, and the necessity for taking the personal equation into consideration in passing judgment on such reports. He concludes that it is evident that in no one of the diseases considered has there yet been demonstrated an entirely satisfactory serum therapy. Although sufficient beneficial results have been obtained with some of the streptococcic, dysenteric, plague and anthrax antiserums to warrant at least some hope of better results when

As soon as the trouble is properly diagnosed the limb should be placed in a box or wire splint and well covered with cotton wool, first powdering it with the following:

℞. Acidi boracici	ʒiii	12
Pulv. talci	℥iii	90

M. Ft. pulvis. Sig.: Dust over the affected limb before applying the splint.

He does not recommend the local application of ointments as usually recommended during this stage, but prefers the dry treatment. Milk should be the principal article of diet. At the end of three weeks or a month the second stage, as mentioned by the author, begins, when the splint should be removed from the limb and the limb gently rubbed with a lubricant such as lanolin or oil of theobroma, and again enveloped in cotton wool and allowed to rest on a support for three days. If at the end of that time no pain is felt or any rise of temperature observed, the covering may be removed and the following gently applied locally once a day:

℞. Ext. hamamelidis flu.	ʒss	2
Lanolini	℥i	30

M. Ft. unguentum. Sig.: Apply locally to the affected limb.

At this period the limb may be given massage in a gentle manner to promote the general circulation. It must be done lightly with the palm of the hand for five or six minutes once a day. In order to facilitate resolution the following may be rubbed in every evening:

℞. Ergotin	ʒi	4
Kalii iodidi		
Ext. nucis vom., āā	ʒss	2
Lanolini	℥i	30

M. Ft. unguentum. Sig.: Apply locally.

After fifteen days of this treatment active and passive movements of the limb are recommended by the author, these consisting in flexion, extension, abduction and rotation of the foot.

The treatment of phlebitis is concluded by the author by applying a bran bath every day for twenty minutes, gradually lengthening the time to forty-five minutes. After the bath the patient must be instructed to rest for half an hour, when massage should be given for ten minutes, followed by a rest of thirty minutes, when the patient may be allowed to take a little exercise on the feet. This treatment may be kept up for three weeks, but the author cautions against giving massage in the region of the large veins, in the popliteal space, in Hunter's canal or in Scarpa's triangle. To promote the nutrition of the atrophied muscles and to improve the venous circulation walking is recommended in moderation, avoiding fatigue. This author forbids the patient standing or sitting down; he must either walk or lie down.

To Prevent the Shedding of Hair.

David Walsh of London, according to an abstract in *Med. Standard*, recommends the following combination to prevent the hair from falling out, stating that it is preferable to an ointment, especialy in the cases of women:

℞. Acidi salicylici	ʒiii	12
Acidi carbolici	ʒi	4
Olei ricini	ʒiii	12
Spts. vini rectif. q. s. ad	℥vi	180

M. Sig.: Apply locally once or twice daily.

Mucus Colitis.

R. C. Kemp, in *Amer. Med.*, recommends in the treatment of mucus colitis that the patient be put to bed and heat applied to the abdomen by means of flaxseed poultices, turpentine stupes or hot pepper poultices, using dram one (4.00) of red pepper to a pint of boiling water, a flannel wrung out of this solution applied to the abdomen and covered with oiled silk. Dry heat may be employed if necessary by means of a hot-water bag, a hot bag of salt or a tin plate heated and covered by flannel and applied to the abdomen. Moist heat, however, is preferable. The greatest relief from the cramp, according to the author, are afforded by enteroclysis, using a recurrent irrigator and the normal saline solution at a temperature of from 110 to 120 F., and adding the oil of peppermint, from five (.30) to fifteen minims (1.00) to the quart of water. Several gallons may be used once or twice in the twenty-four hours, allowing no water to remain in the bowels to excite further cramps. *High enemas of olive oil*, using a pint or a quart of the oil, are also of value in relieving the spasm in similar manner to the relief of spasm of the pylorus by the internal administration of olive oil.

Hot saline enemas containing from two to four ounces (60 to 120) of the milk of asafetida are also of value in relieving the cramps.

Liquid diet, such as broths, soups and milk, should be prescribed. The tincture of belladonna as recommended by all authors is advised, beginning with 10 minim doses every three or four hours, and increasing the dose till the physiologic symptoms occur, is recommended to give relief from the spasms. Occasionally the author resorts to codein in doses of grain 1/4 to grain 1/2 (.015 to .03), or even morphin in doses of grain 1/8 to grain 1/4 (.008 to .015) when the pain is excessive.

If the acute attack is prolonged the valerianates or asafetida are recommended internally and the milk of asafetida as an enema. Between the attacks proper support to the abdomen is advised, producing pressure backward and upward by means of a silk abdominal supporter, or in its stead an adhesive plaster belt. If the latter is used the surface of the abdomen must be smoothly shaven and cleansed with alcohol or ether before the adhesive belt is applied. The belt should be changed about once in four weeks. To relieve constipation enemas of the normal saline solution are recommended several times a week to promote intestinal peristalsis, and in this way to prevent the accumulation of mucus and thus to lessen the tendency to the recurrence of the spasms. He emphasizes the importance of using only the normal saline solutions or the demulcents as enemas for the removal of the mucus, as the condition is due to hypersecretion and not to inflammation. He avoids the use of irrigations of silver, tannin, alum, etc., as they can produce an artificial hypersecretion. Nux vomica or strychnia may be given between the attacks to increase the muscular tone of the intestine. If much gastrointestinal fermentation is present the following combination is recommended:

℞. Resorcini	gr. v	30
Sodii benzoatis		
Bismuthi salicylatis, āā	gr. v-x	30-.65

M. Ft. capsula No. i. Sig.: One such capsule three times a day before food.

W. H. Thomson recommends the following in mixed cases in which some catarrh of the intestine is present:

℞. Argenti nitratis	gr. v	30
Resinæ terebinthinæ	ʒiii	12
Liq. potassæ	ʒi	4
Pulv. glycyrrhizæ q. s.		

M. Ft. pil. No. lx. Sig.: Three pills three times a day.

Copper sulphate grain 1/4 (.015) may be substituted for the foregoing later. Fowler's solution in one-drop (.06) doses three times a day is also recommended in mixed cases.

The general treatment consists in outdoor exercise, such as golf, to strengthen the abdominal muscles, and in winter fencing is of value. Anemia must be corrected by means of Bland's mass combined with small doses of arsenic and nux vomica.

Age or Weight and Personal Injuries.—The Court of Errors and Appeals of New Jersey holds, in the personal injury case of Staines vs. Central Railroad Company of New Jersey, that the fact that the injuries of the plaintiff would not have happened to a younger person, or one of less weight, did not absolve the defendant from liability for such injuries.

Injured Physician May Testify as to Earnings.—The Supreme Court of Missouri says, in the case of Sluder vs. St. Louis Transit Co., where a physician was incapacitated to practice his profession for eleven and one-half weeks by a collision of a street car with a carriage in which he was riding, that no reason was stated why it was not competent for the physician himself to testify what his actual monthly practice averaged him. It was not guesswork, but actual knowledge, to which he was testifying. It was not remote, but the value of his profession to him for the immediate months during which he was disabled, and the court agrees with him that the best evidence was the actual earnings of the month in which he was injured. In other words, the court holds that there was no error in permitting him to testify to his earnings for the corresponding months of the previous year.

Mental Disease Relieving from Criminal Responsibility.—The Supreme Court of Georgia holds, in Allams vs. State, that where the accused on trial for murder relied on the defense of insanity at the time of the homicide, it was not error to instruct the jury that the burden was on him to show "that at the time of the killing he was not of sound memory and discretion. He must show this not beyond a reasonable doubt, but to the reasonable satisfaction of the jury, by a preponderance of the evidence." Nor was it error on the trial of such a case to charge the jury that, if the accused had been shown to be insane prior to the date of the homicide, the presumption would be that he continued to be insane, "and the burden of proof would be on the state to show to the reasonable satisfaction of the jury, by a preponderance of the evidence, that at the time of the alleged homicide the defendant was of sound memory and discretion."

The rule of law in force in Georgia which relieves one from criminal responsibility for the commission of an unlawful act on account of mental disease is: If a man has reason sufficient to distinguish between right and wrong in relation to a particular act about to be committed, he is criminally responsible. An exception to this rule is where a man has reason sufficient to distinguish between right and wrong as to a particular act about to be committed, yet, in consequence of some delusion, his will is overmastered, and there is no criminal intent, provided that the act itself is connected with the peculiar delusion under which the prisoner is laboring. It follows, therefore, that it was not accurate to charge as follows: "The insanity which the law recognizes as an excuse for crime must be such as dethrones reason and incapacitates an individual from distinguishing between right and wrong as to the particular act in question, and of being mentally incapable of choosing to do or not to do the alleged act, and governing his conduct in accordance therewith." To relieve one from criminal responsibility on account of mental delusion for the commission of an unlawful act, it is not necessary that he be incapable of distinguishing right from wrong as to the particular act in question, and also incapable of choosing to do or not to do such act, and of governing his conduct in accordance therewith.

Alcoholic Compounds Labeled as Medicines.—The United States Commissioner of Internal Revenue says, in Internal Revenue Circular No. 673, dated Sept. 12, 1905, addressed to collectors of internal revenue, with regard to alcoholic compounds labeled as medicines and held out to the public as remedies for diseases.

Among the various alcoholic compounds now on the market, advertised and sold under the name of whisky, bitters, tonic, cordials, etc., there are some that are composed chiefly of distilled spirits, or mixtures thereof, without the addition of drugs or medicinal ingredients in sufficient quantities to change materially the character of the alcoholic liquor.

The fact that these compounds during the existence of the statute imposing tax on proprietary medicines were without the necessity of investigation into their character by the terms of the law made subject to that tax, because they were held out to the public as medicines, does not afford ground for relieving the manufacturers from special tax as rectifiers and liquor dealers, or dealers therein from special tax as liquor dealers under the provisions of Section 3244, Revised Statutes, and amendments.

It is held that the statute requires the exaction of this special tax from the manufacturer of every compound of distilled spirits, even though drugs are declared to have been added thereto, when their presence is not discoverable by chemical analysis, or it is found that the quantity of drugs in the preparation is so small as to have no appreciable effect on the alcoholic liquor of which the compound is mainly or largely composed.

The same ruling applies to every alcoholic compound labeled as a remedy for diseases and containing, in addition to distilled spirits, only substances or ingredients which, however large their quantity, are not of a character to impart any medicinal quality to the compound; but where substances undoubtedly medicinal in their character are combined with whisky or other alcoholic liquor, and are used in sufficient quantity to give a medicinal quality to the liquor other than that which it may inherently possess, such compound is, of course, not to be included in this ruling.

The question, in each case, arising under the terms of this circular will be determined by this office, not merely on examination of the formula submitted by the manufacturer of the compound, but on result of the analysis in the chemical laboratory here of samples obtained in the open market and sent in by the local internal revenue officers and agents.

The ruling as to these compounds in the fourth paragraph of Circular No. 608 (Treasury Decisions, 1901, Vol. 4, p. 210), "that if they are composed of spirits in combination with drugs, herbs, roots, etc., and are held out as remedies for diseases stated in labels on the bottles, they are to be regarded as medicines until the facts ascertained, as to the purpose for which they are usually sold or used, show them to be beverages, and until such facts are obtained druggists and merchants who sell these compounds in good faith as medicines only are not to be called on to pay special tax as liquor dealers on account of such sales," is hereby revoked.

But in order that no injustice may be done to these druggists and merchants who, without holding special-tax stamps as liquor dealers, now have in stock these compounds for sale as medicines, this circular will not be put into effect until Dec. 1, 1905.

Collectors will, however, immediately on the receipt of this circular send out notice to all druggists and merchants dealing in proprietary medicines in their districts who do not hold the requisite special-tax stamp as liquor dealers, that on and after Dec. 1, 1905, they will be required to pay special tax for selling the alcoholic compounds coming within the ruling now promulgated, even when they sell them in good faith for medicinal use only, never selling them as beverages, nor selling them knowingly to those buying them for use as beverages. [In this connection, see editorials Sept. 23 and 30, 1905.]

7 *[illegible]f Cleft Palate and the Causes of Fail- [illegible] Pittsburg, Pa.

2. **Therapeutic Value of Bactericidal Serums.**—Pease reviews some of the clinical results obtained by the use of the various antistreptococcic serums in streptococcus infections, scarlet fever, rheumatism and smallpox, and the antipneumococcic, antityphoid, antituberculosis, antidysenteric, antiplague and antianthrax serums in their respective diseases, and calls attention to the variability in the reports of different writers on their results from the use of these serums, and the necessity for taking the personal equation into consideration in passing judgment on such reports. He concludes that it is evident that in no one of the diseases considered has there yet been demonstrated an entirely satisfactory serum therapy. Although sufficient beneficial results have been obtained with some of the streptococcic, dysenteric, plague and anthrax antiserums to warrant at least some hope of better results when

our knowledge of these infections and their etiologic agents has become materially increased.

3. **Gastrojejunostomy for Benign Stenosis of Pylorus.**—Morrison reports the case of a man, aged 44, who came under observation when he was suffering from a sudden attack of severe hematemesis. He had had three previous attacks at intervals of about one year; in the intervening periods he was fairly well and able to work. There had been considerable digestive disorder with frequent attacks of vomiting. Examination showed marked dilation of the stomach, the greater curvature extending two inches below the umbilicus. There was no tenderness and no tumor could be detected. The contraction of the pylorus increased until apparently nothing passed into the intestine, all food taken being vomited after a longer or shorter interval. The abdomen was opened in the median line and a communication established between the posterior part of the stomach and the jejunum, four inches from the duodenojejunal fold, a large-sized Murphy button reinforced by a continuous peritoneal suture being employed. Recovery was uneventful.

5. **Emotional Shock and Fright as Causes of Epilepsy.**—According to Spratling, emotional shock and fright, as causes of epilepsy, do not receive the attention they should. Epilepsy may supervene immediately after the application of such a cause or be delayed for some time. The reapplication of the primary cause often induces successive attacks similar in nature. Predisposition usually exists in all such cases. In 1,323 cases Spratling found emotional shock or fright to have been the cause in 62 cases, 5.5 per cent. Of these patients, 22 were males in a total of 814, and 40 were females in a total of 509, being 3 per cent. of the former and 8 per cent. of the latter. This shows such causes to be nearly three times as active among men as among women. This greater susceptibility in women is present from childhood. During the first ten years of life there were 14 cases due to this cause among 814 males, and 15 cases among 519 females. After the twentieth year there was only one case in either sex. It appears from the studies in question that emotional shock or fright most often leads to epilepsy in the female sex, and that these factors are most apt to be active about the age of puberty.

7. **Operative Treatment of Cleft Palate.**—Singley states that the results in the operative treatment of cleft palate are almost certain to be good if accurate approximation can be secured and maintained without tension. From three to five months before operation a dentist places in the three upper posterior molars a small metal clamp, the two sides of which can be gradually approximated by a screw and nut, thus diminishing the width of the cleft. The clamp is removed a few days before operation. The edges of the cleft are split laterally, using a small knife with a flexible copper shank, thus securing broader surfaces for union. The relaxation incisions on either side are kept packed with strips of iodoform gauze, preventing contraction during healing of these incisions with pulling on the suture line. A marked Trendelenburg posture is used with the head of the patient just above the knees of the operator. Proper postoperative treatment ranks next in importance to approximation without tension. This comprises absolute starvation for two or three days with nutritive enemas, absolute prohibition of talking, and frequent irrigation of the parts with a mild antiseptic solution. The gauze packing is removed and replaced daily.

Medical News, New York.

September 16.

8 *A Test of Condition: Preliminary Report. C. W. Crampton, New York.
9 Intussusception. W. E. Dicken, Oklahoma City, O. T.
10 Retained Intubation Tube Treated by Gradual Dilatation. F. L. Taylor, New York.
11 Dermoid Cysts of the Mediastinum. R. S. Morris, Ann Arbor, Mich.
12 Diagnosis and Differential Diagnosis of Incipient Pulmonary Tuberculosis. H. F. Stoll, Hartford, Conn.
13 *Rod Auscultation. E. Reichmann, Berlin, Germany.

8. **Test of Condition.**—For the *purpose of determining* the real condition or relative degree of health of an individual, Crampton has devised a condition test. The patient is directed to lie down flat on a couch with no head rest. The armlet of the blood pressure instrument is then placed around the upper arm. This should be arranged so that it bears the same relation to the heart lying as it will when the patient is standing, so that no hydrostatic error will be included. Absolute quiet is insisted on, relaxation of the muscles is necessary, and all emotional disturbances should be guarded against. The pulse rate is then taken by quarter minutes for at least four successive quarters. These should be recorded until a plateau is arrived at in which the heart is steady, the indication of which may be taken to be the point where four records show no decrease. These four records forming a minute's record should be noted for comparison with the standing rate. Without releasing the grip on the radial artery, the systolic pressure should be taken. This should be taken twice, and if any great difference is noted, a third time, and the average struck. If there is any considerable variation noted, it may be due to several disturbing factors, such as an uncomfortable position, emotional disturbances, nervous muscular contractions, holding the breath, etc., all of which should be eliminated. These items recorded, the patient is allowed to stand and the same records taken in the same way with the same precautions. It is important that the pulse rate should be allowed to fall to its standing normal after rising, for it is accelerated by the muscular act of getting up. The blood pressure also rises considerably at first *(though it may fall)*, but it strikes a balance, as a rule, a little before the pulse rate does. Compare results and arrive at a conclusion as to the condition of the individual. The whole test takes less than five minutes. It is advisable, at first, to repeat the test and to corroborate the findings of the first examination; with little practice, however, a repetition is unnecessary. By the use of this test one can estimate the progress made in chronic cases and the value of the remedies applied. It is inapplicable to any but ambulant cases, for rest in bed interferes with it strongly. A moderate amount of rest in the run-down will increase the efficiency of the vasomotor mechanism, but long-continued rest decreases its efficiency, from disuse, to a marked extent. The fall of cerebral pressure and consequent syncope caused by even the sitting up in bed of a patient long recumbent is familiar to all. Its chief use in future will no doubt be in the diagnosis of the amount of damage to the general vitality of any hidden disease or any course of life has produced in the patient under observation for the first time, and also in the estimation of the progress made under treatment. In therapeutics it is not enough to know how a drug affects the blood pressure; the physician must know how it affects the vasomotor control. Crampton has applied this test to a number of hard-worked business and professional men with most satisfactory results. In every case it formed an accurate and reliable index to real improvement. It was very much steadier in its readings than would be expected from the apparent variations in observed *condition*, which were extremely variable, but it seemed to check real improvement much more positively than could be determined by observation. In one case of neurasthenia, in which a relative degree of sexual impotence was a symptom, the index followed the regaining of this function very exactly, and marked a relapse as accurately.

13. **Rod Auscultation.**—To practice Reichmann's method, a small rod of special design is applied firmly and vertically to the surface of the body, and the top of the middle finger is passed with moderate force over the rod, while it is steadied with the thumb and index finger. This friction produces, in the rod, vibrations—sound-waves—which, in accordance with well-known physical laws, are transmitted in every direction. Hence they pass also on the surface of the body, and, if sufficiently strong, into the subjacent organs, from which they are again transmitted in every direction. If then a stethoscope be *placed near the rod, with* the ear applied thereto, these sound waves can be heard, and a sound of a peculiarly *grating* character, resembling somewhat the noise produced when a finger is passed over silk or similar material, is noted. If the skin is soft and not tense, the sound waves can pass through it for only a very short distance, and likewise they can not go very far in the loose subcutaneous tissue. If they encounter an underlying contracted muscle, or,

for instance, a rib, they will naturally be transmitted into the structure, and, according to its course, continue in it, becoming audible nearly over the full extent of this muscle or rib, provided that both stethoscope and rod are placed over the same structure; an internal organ under these conditions will, therefore, not be able to influence the audibility of the sound waves. The conditions are different if a muscle or a rib does not intervene between the internal organ and the stethoscope and rod, or if either the stethoscope or the rod is applied so as to avoid a muscle or rib. In this case, then, *it is impossible for the sound-waves to be transmitted through the latter from the rod to the stethoscope*, and the examination of the internal organ is no longer disturbed thereby. Since the sound waves are transmitted in every direction in this internal organ, the sound produced by them can be heard as long as stethoscope and rod are over this organ, and cease to hear them when one or the other has left the organ; this for the reason that the waves being reflected *at the boundary of the organ, at the serous covering*, are thus prevented, or nearly so, from passing to an adjacent organ; hence, the sound that is heard becomes more dull and now resembles the noise produced by a finger passing over rubber or similar substances. Small organs are but little suited for rod auscultation, as transmission through the skin and the surface of the body is most likely to interfere with the examination. The heart also, in most instances, can not be outlined with sufficient exactness by this method. This is more especially true of the right and left boundaries of the heart because transmission through the ribs too often plays a disturbing part and vitiates the findings. The upper and the lower boundaries are more readily determined. It is much easier to examine the lungs. By means of rod auscultation *it is possible also to differentiate the individual lobes of the lungs*, provided they do not coalesce with one another. It is equally possible to determine the boundaries of the liver readily and accurately if the abdominal muscles are not tense, and especially when that organ is somewhat hard, and firm organs better conductors than flaccid and soft ones. The *method is of special value in cases in which the diagnosis is somewhat in doubt* and in which it becomes a matter of importance to clear this up, as, for instance, whether an abdominal tumor that has been definitely made out has its origin in the liver or is merely situated in its vicinity—a point that can not always be determined by palpation and percussion. The change of the *friction sound* in this case is bound to occur very distinctly between liver and tumor if the tumor does not coalesce with the liver; the change will not take place if it does so coalesce; the sound waves in the latter instance encounter no obstacle from which they are reflected.

14. **Diagnosis of Diseases of the Nervous System.**—Collins says that the reasons why nervous diseases are considered to be a strange country by the general practitioner are: (1) Because there is an inherited conviction that such diseases are extremely obscure; (2) because there is an acquired conviction that in order to unravel the intricacies of such diseases, a comprehensive knowledge of the anatomy and physiology of the nervous system is required; and (3) because many physicians do not take the trouble to acquaint themselves with the simple methods of testing for the existence of nervous disease. He explains that this is a mistaken standpoint and shows that nervous diseases, if approached with the same care that is necessary for the study of other affections, are no more difficult or obscure than most medical problems. Any medical man who will free himself from his preconceived ideas of the difficulties of the subject will have no more difficulty in dealing satisfactorily with nervous diseases than he has with any other disease in the province of internal medicine. The diagnosis of the commoner and more important nervous maladies is analyzed at length, for each condition, and illustrative cases are cited.

15. **Laryngeal Diphtheria Complicating Cerebrospinal Meningitis.**—Simpson reports a case of laryngeal diphtheria which existed at the same time with cerebrospinal meningitis and did not modify the disease. This occurred at the time when the attempt was being made to modify the cerebrospinal meningitis by the use of diphtheria antitoxin. The patient had all the classical symptoms of cerebrospinal meningitis, when she began to complain of hoarseness, croupy cough and dyspnea. There was no membrane in the pharynx or on the tonsils, but pieces of membrane were coughed up in which the Klebs-Loeffler bacillus were found, in pure cultures. Intubation became necessary, and antitoxin was administered with good effect on the diphtheria, but without modifying the symptoms of the other disease in any way. Lumbar puncture was also performed on three occasions. The case went to irregular heart action and high temperature, and the patient developed pneumonia with fatal result.

17. **Influence of Pneumococci on Wound Healing.**—Robinson describes cases in which severe infections with pure cultures of pneumococci went on to a very favorable outcome. He concludes that (1) The pneumococci, if alone, cause little inflammatory reaction in the healing of wounds. (2) Possibly, in surgical diseases caused by pneumococci, some protective substance is formed that ameliorates the symptoms, as occurs in the crisis of a pneumonia. (3) In the treatment of a pus case care should be used to prevent a mixed infection, as healing is much more apt to be rapid and smooth if only one variety of bacteria is present.

19. **Aortic Reflexes.**—Abrams considers the *aortic reflexes* of great importance in medical diagnosis. To get these reflexes the palm of one hand is applied closely to the spinous processes, while the other clenched fist is used as a percussion hammer, using sharp, vigorous blows. For the reflex of dilatation he concusses the spinous processes of the eighth, ninth, tenth, eleventh and twelfth dorsal vertebræ. Then he quickly percusses the region of the thoracic aorta, and the course of that vessel is easily defined. This is a curved line beginning at the right sternal line in the middle of the first intercostal space, and ending at the point of insertion of the first rib to the sternum. The highest point is about 5 centimeters from the anterior thoracic wall, and the beginning 2 centimeters from it. Concussion *of the seventh cervical vertebra* causes aortic dullness to evanesce at once, as a result of the cause there is an inherited conviction that such diseases are fairly constant but variable in duration.

20. **Trichocephalus in Typhoid.**—Spezia made observations in 19 cases of typhoid, in 17 of which he found eggs of trichocephalus in the feces. In other diseases of the gastrointestinal tract these eggs are rare. The author believes that the trichocephalus inflicts wounds on the intestines, which permit of the entrance of the *Bacillus typhosus* in the intestinal wall. In view of these facts, it will be necessary, in typhoid fever, to use disinfectants capable of dissolving the resistant covering of these eggs, as well as of destroying the bacillus of Eberth; such, the author holds, are concentrated solutions of potassium and sodium salts.

21. **Causes of Disability After Fractures of Leg and Ankle.**—As the result of a careful study of 47 cases, Cotton found

our knowledge of these infections and their etiologic agents has become materially increased.

3. Gastrojejunostomy for Benign Stenosis of Pylorus.—Morrison reports the case of a man, aged 44, who came under observation when he was suffering from a sudden attack of severe hematemesis. He had had three previous attacks at intervals of about one year; in the intervening periods he was fairly well and able to work. There had been considerable digestive disorder with frequent attacks of vomiting. Examination showed marked dilation of the stomach, the greater curvature extending two inches below the umbilicus. There was no tenderness and no tumor could be detected. The contraction of the pylorus increased until apparently nothing passed into the intestine, all food taken being vomited after a longer or shorter interval. The abdomen was opened in the median line and a communication established between the posterior part of the stomach and the jejunum, four inches from the duodenojejunal fold, a large-sized Murphy button reinforced by a continuous peritoneal suture being employed. Recovery was uneventful.

5. Emotional Shock and Fright as Causes of Epilepsy.—According to Spratling, emotional shock and fright, as causes of epilepsy, do not receive the attention they should. Epilepsy may supervene immediately after the application of such a cause or be delayed for some time. The reapplication of the primary cause often induces successive attacks similar in nature. Predisposition usually exists in all such cases. In 1,323 cases Spratling found emotional shock or fright to have been the cause in 62 cases, 5.5 per cent. Of these patients, 22 were males in a total of 814, and 40 were females in a total of 509, being 3 per cent. of the former and 8 per cent. of the latter. This shows such causes to be nearly three times as active among men as among women. This greater susceptibility in women is present from childhood. During the first ten years of life there were 14 cases due to this cause among 814 males, and 15 cases among 519 females. After the twentieth year there was only one case in either sex. It appears from the studies in question that emotional shock or fright most often leads to epilepsy in the female sex, and that these factors are most apt to be active about the age of puberty.

7. Operative Treatment of Cleft Palate.—Singley states that the results in the operative treatment of cleft palate are almost certain to be good if accurate approximation can be secured and maintained without tension. From three to five months before operation a dentist places in the three upper posterior molars a small metal clamp, the two sides of which can be gradually approximated by a screw and nut, thus diminishing the width of the cleft. The clamp is removed a few days before operation. The edges of the cleft are split laterally, using a small knife with a flexible copper shank, thus securing broader surfaces for union. The relaxation incisions on either side are kept packed with strips of iodoform gauze, preventing contraction during healing of these incisions with pulling on the suture line. A marked Trendelenburg posture is used with the head of the patient just above the knees of the operator. Proper postoperative treatment ranks next in importance to approximation without tension. This comprises absolute starvation for two or three days with nutritive enemas, absolute prohibition of talking, and frequent irrigation of the parts with a mild antiseptic solution. The gauze packing is removed and replaced daily.

8. Test of Condition.—For the purpose of determining the real condition or relative degree of health of an individual, Crampton has devised a condition test. The patient is directed to lie down flat on a couch with no head rest. The armlet of the blood pressure instrument is then placed around the upper arm. This should be arranged so that it bears the same relation to the heart lying as it will when the patient is standing, so that no hydrostatic error will be included. Absolute quiet is insisted on, relaxation of the muscles is necessary, and all emotional disturbances should be guarded against. The pulse rate is then taken by quarter minutes for at least four successive quarters. These should be recorded until a plateau is arrived at in which the heart is steady, the indication of which may be taken to be the point where four records show no decrease. These four records forming a minute's record should be noted for comparison with the standing rate. Without releasing the grip on the radial artery, the systolic pressure should be taken. This should be taken twice, and if any great difference is noted, a third time, and the average struck. If there is any considerable variation noted, it may be due to several disturbing factors, such as an uncomfortable position, emotional disturbances, nervous muscular contractions, holding the breath, etc., all of which should be eliminated. These items recorded, the patient is allowed to stand and the same records taken in the same way with the same precautions. It is important that the pulse rate should be allowed to fall to its standing normal after rising, for it is accelerated by the muscular act of getting up. The blood pressure also rises considerably at first (though it may fall), but it strikes a balance, as a rule, a little before the pulse rate does. Compare results and arrive at a conclusion as to the condition of the individual. The whole test takes less than five minutes. It is advisable, at first, to repeat the test and to corroborate the findings of the first examination; with little practice, however, a repetition is unnecessary. By the use of this test one can estimate the progress made in chronic cases and the value of the remedies applied. It is inapplicable to any but ambulant cases, for rest in bed interferes with it strongly. A moderate amount of rest in the run-down will increase the efficiency of the vasomotor mechanism, but long-continued rest decreases its efficiency, from disuse, to a marked extent. The fall of cerebral pressure and consequent syncope caused by even the sitting up in bed of a patient long recumbent is familiar to all. Its chief use in future will no doubt be in the diagnosis of the amount of damage to the general vitality of any hidden disease or any course of life has produced in the patient under observation for the first time, and also in the estimation of the progress made under treatment. In therapeutics it is not enough to know how a drug affects the blood pressure; the physician must know how it affects the vasomotor control. Crampton has applied this test to a number of hard-worked business and professional men with most satisfactory results. In every case it formed an accurate and reliable index to real improvement. It was very much steadier in its readings than would be expected from the apparent variations in observed condition, which were extremely variable, but it seemed to check real improvement much more positively than could be determined by observation. In one case of neurasthenia, in which a relative degree of sexual impotence was a symptom, the index followed the regaining of this function very exactly, and marked a relapse as accurately.

13. Rod Auscultation.—To practice Reichmann's method, a small rod of special design is applied firmly and vertically to the surface of the body, and the top of the middle finger is passed with moderate force over the rod, while it is steadied with the thumb and index finger. This friction produces, in the rod, vibrations—sound-waves—which, in accordance with well-known physical laws, are transmitted in every direction. Hence they pass also on the surface of the body, and, if sufficiently strong, into the subjacent organs, from which they are again transmitted in every direction. If then a stethoscope be placed near the rod, with the ear applied thereto, these sound waves can be heard, and a sound of a peculiarly grating character, resembling somewhat the noise produced when a finger is passed over silk or similar material, is noted. If the skin is soft and not tense, the sound waves can pass through it for only a very short distance, and likewise they can not go very far in the loose subcutaneous tissue. If they encounter an underlying contracted muscle, or, for instance, a rib, they will naturally be transmitted into the structure, and, according to its course, continue in it, becoming audible nearly over the full extent of this muscle or rib, provided that both stethoscope and rod are placed over the same structure; an internal organ under these conditions will, therefore, not be able to influence the audibility of the sound waves. The conditions are different if a muscle or a rib does not intervene between the internal organ and the stethoscope and rod, or if either the stethoscope or the rod is applied so as to avoid a muscle or rib. In this case, then, it is impossible for the sound-waves to be transmitted through the latter from the rod to the stethoscope, and the examination of the internal organ is no longer disturbed thereby. Since the sound waves are transmitted in every direction in this internal organ, the sound produced by them can be heard as long as stethoscope and rod are over this organ, and cease to hear them when one or the other has left the organ; this for the reason that the waves being reflected at the boundary of the organ, at the serous covering, are thus prevented, or nearly so, from passing to an adjacent organ; hence, the sound that is heard becomes more dull and now resembles the noise produced by a finger passing over rubber or similar substances. Small organs are but little suited for *rod auscultation*, as transmission through the skin and the surface of the body is most likely to interfere with the examination. The heart also, in most instances, can not be outlined with sufficient exactness by this method. This is more especially true of the right and left boundaries of the heart because transmission through the ribs too often plays a disturbing part and vitiates the findings. The upper and the lower boundaries are more readily determined. It is much easier to examine the lungs. By means of rod auscultation it is possible also to differentiate the individual lobes of the lungs, provided they do not coalesce with one another. It is equally possible to determine the boundaries of the liver readily and accurately if the abdominal muscles are not tense, and especially when that organ is somewhat hard, and firm organs better conductors than flaccid and soft ones. The method is of special value in cases in which the diagnosis is somewhat in doubt and in which it becomes a matter of importance to clear this up, as, for instance, whether an abdominal tumor that has been definitely made out has its origin in the liver or is merely situated in its vicinity—a point that can not always be determined by palpation and percussion. The change of the friction sound in this case is bound to occur very distinctly between liver and tumor if the tumor does not coalesce with the liver; the change will not take place if it does so coalesce; the sound waves in the latter instance encounter no obstacle from which they are reflected.

26 Ocular Vertigo of Interest to the General Practitioner. B. P. Croft, Greenfield, Mass.

21. **Causes of Disability After Fractures of Leg and Ankle.**—As the result of a careful study of 47 cases, Cotton found

that the chief causes of disability in leg and ankle fractures are: (1) Failure to preserve the line of the limb—and consequent static trouble. (2) Mechanical damage to the ankle joint. (3) Static trouble from overload on atrophied muscles—apart from any malposition. (4) Contractures. The tendency to malposition must be guarded against, first by careful study of lesions and by careful reduction; second, by careful review (checked, if possible, by *x*-rays) of the result of reduction and of the present condition—a review to be made after, not over two or three weeks, when swelling and spasm are gone, yet while correction of mistakes is still easy. Later, operations are the only resort—undesirable, yet they are often of great service. The pure static troubles independent of malposition are usually readily relieved by careful plate support. Cotton believes that the contractures are avoidable in all cases unless there is long-continued tendency to recurrence of deformity or delayed union or extreme trauma affecting soft parts as well as bone. In his opinion they call for treatment directed toward preserving flexibility and nutrition of the muscles, instituted before fixation has rendered the early spastic changes permanent. This means that rigid plaster bandages must be made removable at from two to four weeks, not at three months, and that exercises without weight bearing must be performed persistently under proper supervision. If this is not done, stiffness of ankles and less often of the knees must be expected as one of the great factors of disability.

25. **Therapeutic Value of Hydrochloric Acid in Stomach Affections.**—Chase gave 20 minims of HCl in 90 c.c. of water, two or three times, at fifteen-minute intervals, after an Ewald test breakfast. One hour after the meal was given the gastric contents were withdrawn and the acidity tested. Four tests were made. The total acidity was always increased, and in three of the four tests, free HCl was present in appreciable amounts. In one test it was absent. From 15 to 25 minims of HCl were given in 90 c.c. of water three times within an hour after the ingestion of a large meat sandwich, and 300 c.c. of water. Nine tests were made. In from sixty to seventy minutes after the meal was given, the total acidity of the gastric contents was always found increased, but free HCl vas never present. Chase also found that the long-continued ıse of large doses (45 drops, three times daily), of HCl diminished the total acidity. He believes that the HCl has a [illegible]ressing influence on the gastric acidity which is not gen[illegible]y recognized. Peptic digestion, however, is accelerated [illegible]he use of HCl, although in certain conditions large doses [illegible]ome manner retard peptic digestion. He is of the opinion [illegible] while large doses of HCl often alleviate certain symptoms, [illegible] never improve any function of the stomach.

35 [illegible] of Infancy. L. Johnson, Washington.

28. **Floating Kidney Due to Colon Displacement.**—A case of this kind is reported by Chandler. The left kidney was normal and in position. The right kidney was absent from its position. The small intestines and appendix were apparently normal, but the entire first portion of the large intestine was movable, and adherent to it was a tumor believed to be the absent right kidney. When the kidney space was opened it was impossible to find the kidney, yet it was readily felt in the anterior abdominal cavity. It was judged, therefore, to be free in this cavity, attached to the ascending colon, and this proved to be true. The intestine, in being displaced during pregnancy two years previously, had drawn the kidney with it, and gradually the peritoneum had closed behind the kidney, forming a pedicle carrying the vessels and ureter.

29. **Epilepsy and Eyestrain.**—Spratling cites one case for the purpose of calling attention to the fact that the wearing of glasses seemed to repress the epileptic attacks in a manner not dissimilar to the repression that is often secured by the use of bromids, and that like bromids, while they may mitigate the disease, they are without power to cure. Spratling says that he has yet to see a case of genuine epilepsy cured by correction of ocular abnormalities or by the use of bromids alone.

30. **Convenient Method of Leucocyte Counting.**—Gros designates this as the acetic acid and gentian violet method. The solutions used are: (1) Aqueous solution acetic acid, 5 to 1,000—30 grams; (2) saturated alcoholic solution of gentian violet, 10 drops. The best instrument to use for the count is Hayem's hematimeter. In addition, one must have a pipette for measuring 20 cm. of blood. Also one for measuring .5 *c.c. of the acetic-gentian-violet solution.* Another necessary accessory is a small glass-stoppered tube, containing about 1 c.c., in which the mixture is kept to be examined either at the bedside of the patient or at the doctor's office any time between one-half hour to three hours after the blood has been drawn. The acetic acid dissolves the red blood corpuscles, and the leucocytes alone appear in the microscopic field. The gentian violet is not strong enough to color strongly the whole leucocyte, but it makes the nuclei very visible and allows one not only readily to make the count, but also rapidly to determine the relative number of uninuclear and multinuclear cells.

42. **Blood in Scarlet Fever.**—The investigations made by Tileston and Locke include the study of the blood of 34 cases of scarlatina, 28 of the patients being between the ages of 2 and 10 years, 1 under 2 years, and the remaining 5 varying from 11 to 23 years. Since the patients were observed in hospital wards, it was seldom possible to make an examination of the blood previous to the second or third day, as the patients usually did not enter until the disease was well developed. On the other hand, the examinations once begun were continued until death in the fatal cases, or until the establishment of complete convalescence in those ending in recovery. Only such cases were selected as gave unmistakable evi-

dence of the disease and remained under a constant diet and treatment. In no instance was any medication used other than small doses of strychnia, and even that in but few. The blood was taken about 9.30 a. m. or 4 p. m., in order to avoid any possible influence by the ingestion of food. The authors found that the blood of scarlatina in children differs from that in adults only in proportion to the differences in normal blood at the different ages. A slight secondary anemia is the rule in all but the very mild cases, varying directly with the severity and duration of the disease. The fall in hemoglobin is from 5 to 25 per cent., and in the erythrocytes from 100,000 to 700,000 per cm. Both return to normal after a period of several weeks. A hyperleucocytosis almost invariably accompanies the disease, and runs a characteristic course. Rising abruptly from the second to eighth day (18,000 to 40,000 per cm.) the count falls rapidly for a few days, then more gradually to reach normal in convalescence, usually at the end of from three to six weeks. During the period of invasion and eruption, the polynuclear leucocytes are both relatively and absolutely increased, but decrease gradually with the fall in the leucocytes till convalescence, when they may become relatively, though never absolutely, below normal. The mononuclears take an exactly opposite course. With the onset the eosinophiles disappear entirely or are greatly reduced, to rise above normal when defervescence begins. This eosinophilia persists until late convalescence. Myelocytes are often seen in small numbers, as in all infectious diseases. Complications, with a few exceptions, exert no influence on the course of the blood. If severe, they may increase the anemia, and in a few instances (nephritis and diphtheria) may even produce a rise in the leucocytes.

46. **Nitrate and Nitrite Content of Witte's Peptone.**—Wherry concludes that nitrites, and probably nitrates also, may gain entrance to artificial media from various sources—certain waters, "peptones" and filter papers—yielding distinct reactions for nitrites with naphthylamine hydrochlorid and sulphanilic acid. A sufficient quantity of nitrites may be further absorbed, in a few days, from the laboratory atmosphere, to yield a distinct indol reaction on the addition of 0.5 c.c. of chemically pure sulphuric acid to, for example, a culture of *Bacillus coli communis* 577 grown for twenty-four hours at from 36 to 37 C. in 10 c.c. of Dunham's peptone solution, which originally contained insufficient nitrite to yield such a reaction. The cholera spirillum does not produce nitrites in nitrate and nitrite-free "peptone" solution, prepared from Witte's "peptone" dialyzed free from nitrites; and when nitrites apparently are formed, their presence may be explained by the simultaneous testing of uninoculated controls. The vermilion-colored "cholera red reaction" must be distinguished from the purple-colored "indol reaction." The production of "cholera red," by the cholera spirillum or *Bacillus coli commuis*, takes place only, under the conditions of these experiments, during the reduction of a trace of nitrates, and when formed is demonstrable as such, whether pure sulphuric acid alone or sulphuric acid and nitrite are added, although an excess of nitrite furnishes enough nitrous acid to obscure the reaction. The growth of the *Bacillus coli communis* or of the cholera spirillum in the presence of sufficient nitrite to yield the indol reaction on the addition of a pure acid alone does not influence the character of the indol formed; but if a considerable amount of nitrite be present in the medium, the further addition of nitrite yields enough nitrous acid to obscure the indol reaction. The cholera red reaction is not specific. It is recommended that media used in testing for the production of indol or cholera red be examined for nitrates and nitrites before used.

49. **Typhoid Bacillus in Lung Complications in Typhoid.**—Robinson noted carefully the clinical history and course of several cases of typhoid which succumbed with symptoms indicating a pulmonary complication. A study of the postmortem findings in these cases, as well as a review of cases recorded in the literature, lead Robinson to draw the following conclusions: The typhoid bacillus not infrequently invades the lung during typhoid fever. It may invade areas of the lung already the seat of hemorrhagic infarction and there produce abscess formation and gangrene. The organism may cause bronchopneumonia, but lobar pneumonia as a complication of typhoid fever is usually due to the pneumococcus. This organism may be present as a general infection in the circulating blood simultaneously with the *Bacillus typhosus.* It is probable that both *Bacillus typhosus* and *Bacillus para typhosus*, type *B*, can produce a massive pneumonia, lobar in type. When these organisms are the causative factors, the pneumonia is of a peculiar hemorrhagic character, which may be recognized clinically from the bloody nature of the sputum. The typhoid bacillus is not infrequently found in the sputum of typhoid fever patients with pulmonary complications. This fact should be emphasized in order that spread of the disease by this means may be prevented.

58 *Intussusception. M. H. Richardson and F. W. Palfrey, Boston, Mass.
59 Management of Uterine Fibroids. B. B. Davis, Omaha, Neb.

53. **Conservation of Ovaries and Uterus.**—Tuffier pleads for the saving of the ovaries in certain adnexal diseases. His conclusions are based on 28 cases in which he has practiced conservatism. He is satisfied that the diagnosis of sclerocystic ovaries has concealed diagnostic mistakes, and has justified many useless operations. He believes that this condition is more often dependent on disturbances of ovarian vascularization than on infection, hence he removes these ovaries only in exceptional instances. His technic is as follows: The tube is attacked from the uterus toward the fimbriæ. Forceps are placed on the uterine end of the tube and another forceps without that. He incises between the two, and isolates the uterine angle with its forceps by the aid of a compress. The broad ligament is incised immediately below the body of the tube, thereby removing the tube up to its fimbriæ, carefully isolating the ovary from its salpingo-peritoneal adhesions. Hemostasis must be perfect. The uterine angles and the intrauterine in course of both tubes are destroyed with the thermocautery. The angles are then closed with deep catgut sutures, overlapped with Lembert sutures, thus isolating the uterine mucosa and preventing infection of the neighboring tissues. One extremity of the tubo-ovarian ligament is fixed to the round ligament. The abdominal wall is closed in two layers of the catgut, and the skin is united with hooks. Tuffier has operated according to this method twenty-eight times. The tubal lesions noted at the time of operation were: Salpingitis, with the exception of one case, was always bilateral. Twenty of the cases were suppurative salpingitis, four hematosalpinx, eight cystic, ten interstitial and two tuberculous. The ovaries were apparently sound in 19 cases, somewhat sclerocystic in nine cases. The uterus presented the following appearances: Retroflexed, five times; in normal position, but slightly anteflexed, twenty-three times. In all cases it was infected. If a fungus metritis be present, Tuffier advises curetting the uterus before opening the abdominal cavity. The operative mortality was 3.5 per cent.—one death in 28 cases. This patient died of a late septicemia, due to an effusion of blood in Douglas' cul-de-sac, which suppurated, and was followed by peritonitis. The two postoperative accidents observed had the same origin and the same termination. On the fourth and fifth days the patients had a slight elevation of temperature, some pain, some nausea, some vomiting. Vaginal touch showed that there was an induration of the posterior cul-de-sac. In both cases the posterior cul-de-sac was incised, relief was immediate and cure was complete. Of twenty-eight patients, fifteen have been traced. One suffered some pain despite her regular menses, but she had a tuberculous salpingitis, diagnosed by inspection and by the microscope. Tuffier performed an abdominal panhysterectomy, and found the uterus in place and the left ovary bound to it by a distinct liga-

ment. The right ovary had been removed, the orifices of the tubes were closed and covered with peritoneum, but the whole surface presented tuberculous granulations. One patient had fungus metritis, and had to be curetted. She is now in perfect health. With the exception of these two, all the patients have been remarkably benfited by the intervention.

56. **Study of Acute Phlegmons of the Hand.**—Kanavel presents the results of a most detailed study of fascial space inspection of the hand undertaken for the purpose of demonstrating a means of shortening the course of treatment of pus infections of the hand and producing more fortunate results. Since making these investigations, clinical experience has shown that the course of many cases may be shortened, and that better results may be obtained by taking into consideration the facts demonstrated. The length and thoroughness of the paper prohibits the making of a short abstract, but as a result of this investigation the following facts may be stated: There are five great spaces, with their tributaries, in which pus can accumulate. First, the dorsal subcutaneous, which is an extensive area of loose tissue, without definite boundaries, allowing pus to spread over the entire dorsum of the hand. Second, the dorsal subaponeurotic space, limited on its subcutaneous side by the dense tendinous aponeurosis of the extensor tendons, on the deep side by the metacarpal bones, having the shape of a truncated cone, with the smaller end at the wrist and the broader at the knuckle. Laterally the aponeurotic sheet shades off into the subcutaneous tissue. Third, the hypothenar area, a distinctly localized space. Fourth, the thenar space, occupying, approximately, the area of the thenar eminence, to the flexion adduction crease of the thumb, not going to the ulnar side of the middle metacarpal. It should be remembered that this space lies deep in the palm, just above the adductor transversus. Fifth, the middle palmar space, with its three diverticula below along the lumbrical muscles, limited by the middle metacarpal bone on the radial side, overlapped by the ulnar bursa on the ulnar side, and separated from the thenar space by a partition which is very firm everywhere except at the proximal end, where it is rather thin. A small isthmus can be found leading from the proximal end of the space under the tendons and ulnar bursa at the wrist up into the forearm. Kanavel summarizes his paper as follows: 1. There are certain well-defined, uniform spaces on the fingers, palm, and dorsum of the hand in which pus can accumulate. 2. There are definite anatomic channels by which infection arising in a given spot will extend to certain of these spaces, while certain other spaces will remain uninvolved; hence the diagnosis of the position of the pus is simplified and the proper site for the incision determined. 3. There are definite anatomic channels by which pus can be spread from the uniform spaces mentioned, and when this occurs the position of the pus can be prognosticated. 4. The boundaries of the fascial spaces having been determined, it is readily seen that in some of these the incision for evacuation must be made at definite spots, otherwise important structures may be injured, or by ill-advised incisions adjacent spaces may be opened at the same time, and a spread of the infection favored to parts of the hand that would not become involved without this unfortunate surgical procedure. 5. It can be readily understood why, in certain cases, the infection has persisted for weeks and months after apparently opening the pus pocket, since diverticula and intermediary chambers have not been taken into consideration.

61 Epileptiform Attacks During the Course of Dementia Præcox. P. Masoin, Belgium
62 *Fracture of the First. Second and Third Dorsal Vertebræ; Seven Other Fractures; Laminectomy. G. Hinsdale, Hot Springs, Va.
63 Small Round Cell Sarcoma of the Spinal Column. M. A. Bliss, St. Louis.
64 Family Atrophy of the Peroneal Type. G. L. Walton, Boston.

60. **Acute Anterior Poliomyelitis in a Youth.**—Hoch cites the case of a strong and apparently healthy boy, who after a few days of general indisposition suddenly developed a flaccid paralysis beginning in the leg and within twenty-four hours spreading to the arms. These phenomena were accompanied by a rise in temperature. After a brief acute stage, gradual but slight improvement took place. After thirteen weeks death ensued from pneumonia. The onset of the disease was sudden and there was no history of preceding infectious disease or of exposure.

62. **Paraplegia from Fracture of Upper Three Dorsal Vertebrae.**—Hinsdale's patient sustained ten fractures, including the first, second, and third dorsal vertebræ, the sternum, right clavicle, right radius, left elbow-joint; a compound fracture of the right ankle joint; fracture of the left fibula; dislocation of the left radius at the wrist; fracture of the nose and a lacerated wound of the right brow. During the operation of laminectomy on the second and third, and a part of the fourth dorsal vertebræ, it was found that the arches of these vertebræ were impacted as well as fractured. The fragments were lifted out without much use of the bone forceps, except for trimming. It is now four years since the operation and the patient's condition is a very satisfactory one. She can take long drives and does not show fatigue or any tendency to weakening of the spinal column. She is able to walk with assistance.

68 *Congenital Enterocyst. P. Y. Tupper, St. Louis.

65. **Operation in Hypertrophied Prostate.**—Mudd discusses the time for operative interference and the choice of methods.

67. **Treatment of Diabetes Mellitus.**—Webster calls attention to the dangers and fallacies of an exclusive proteid diet, as well as those of a diet containing a minimum of carbohydrate and an excess of fat. A proper balance of these constituents is as vital to a diabetic as to a normal being, and must be as accurately and as scientifically calculated as possible, if good results are to follow. The dangers of increased glycosuria and acidosis can best be fought by a properly regulated diet; hence every effort should be made to find out just what diet is best suited to the case under treatment. Webster believes that the old diet tables, which did good service in the past, succeeded not because of, but in spite of their characteristics. To cut off carbohydrates to the point of exclusion may be homicidal in some cases, while in others it may be a necessity. The treatment is long and tedious, and if scientifically carried out will yield satisfactory results. It is necessary, however, that the physician should possess a thorough knowledge of the composition of foods, of their absorption, metabolism and excretion. Regarding the signs of approach of coma, Webster advises a very careful examination of the urine for increased ammonia and an administration of $NaHCO_3$ whenever the relation of ammonia nitrogen to total nitrogen equals 10 per cent. or over. Such an excretion means an almost certain danger of coma and should be carefully watched.

68. **Congenital Enterocyst.**—Tupper reports a case of this kind occurring in a girl, aged 13. At birth the child seemed strong and natural in every way, except for the existence of a large sac containing fluid that occupied and protruded from the region of the inferior pelvic outlet. This mass was about four or five inches in its greatest transverse diameter and about 7 or 8 inches in its vertical diameter. On manipulation and pressure the fluid could not be displaced to any extent from the sac, nor were any symptoms referable to the central nervous system produced by such pressure. The sac protruded *posterior* to the rectum and forced this organ and the urogenital tract firmly forward under the pubic arch. When the child was 3 days old the cyst was tapped. It was tapped a second time during the first year of her life. After this there was no great reaccumulation of fluid, the cavity continuing to discharge passively for a time through the trocar opening. At 11 years of age the growth showed irritation from pressure and interfered with the sitting posture, unless the child sat

perfectly upright. The mass was removed by making anterior and posterior flaps extending transversely across its base. At the site of section the original cavity of the cyst had been completely obliterated. The tumor did not form again.

73 *Hemorrhagic Diathesis. C. P. Frantz, Burlington, Iowa.

69. **Removal of Foreign Bodies from Larynx.**—Barclay calls attention to the immediate difficulty with which one may have to contend in attempting forcibly to remove a foreign body, especially a cockleburr, from the larynx, that of the intense reflex laryngeal spasm which may be excited thereby against the sharp spines of the cockleburr. In attempting the removal of such a foreign body, Barclay invokes the aid of an antagonistic reflex—a reflex not only antagonistic to, but far more imperious than that of the dreaded laryngeal spasmodic reflex—namely, that of the demand of the body for oxygen after forced, prolonged expiration. The tissues of the larynx are anesthetized with a cocain solution. The patient is instructed to attempt to phonate the vowel "a," the laryngeal mirror and the Fauvel forceps having been introduced previously. The cockleburr is seized firmly just as the patient phonates, and is held immovably until the patient grows desperate for air, when she is ordered to breathe. The larynx relaxes into the position of forced inspiration, and as it does so a slight wig-wag motion of the forceps will instantly bring away the cockleburr without the loss of a single one of its spines and without wounding the laryngeal tissues.

73. **Hemorrhagic Diathesis.**—Frantz reports two cases of hemophilia, one acquired and the other hereditary, which illustrate the futility of all known methods for checking hemorrhage in a bleeder after tonsillectomy.

Titles marked with an asterisk (*) are abstracted below. Clinical lectures, single case reports and trials of new drugs and artificial foods are omitted unless of exceptional general interest.

British Medical Journal.

September 2.

1 *Educational Number.

The Lancet, London.

September 2.

2 *Students' Number.

1 and 2. **Educational Numbers.**—These issues of the *British Medical Journal* and the *Lancet* contain information for the prospective medical student and the recent graduate. They discuss the financial outlook of the profession of medicine; the profession from the intellectual, ethical and social standpoint; the choice of a medical school; the cost of a medical education; suggestions for the benefit of the medical student as to the books he is likely to find most useful in the course of preparation for his examinations; the course of professional training through which the medical student must pass; the regulations of the general medical college and the medical examining bodies in the United Kingdom; the facilities of the various medical colleges, universities, and hospitals, and such other information as is likely to prove of interest. A statistical study, such as is given annually by The Journal A. M. A., is not undertaken.

The Practitioner, London.

September.

3 *Enlarged Prostate, Its Nature, Smptoms and Treatment. C. Wallace.
4 Incision of the Tympanic Membrane. J. G. Connal.
5 *Hydrocephalus and Posterior Basic Meningitis.* (Concluded.) O. Hildesheim.
6 *Ano Rectal Ulceration. F. C. Wallis.
7 *Remarkable Collection of Foreign Bodies Removed from the *Stomach.* H. H. R. McLeod.
8 Treatment of Venereal Diseases in the Services. P. N. Randall.
9 Value of Pain in Gynecologic Practice. C. Lockyer.
10 Needle in Hand. S. Hastings.
11 *Cultivation of the Parasites of Smallpox and Vaccinia in Vitro. W. E. DeKorte.

3. **Enlarged Prostate.**—Wallace presents a very detailed study of prostatic enlargement, discussing, in turn, the comparative anatomy of the gland, its development and growth in man, functions, external characteristics, structure, the nature of enlargements and their clinical history and treatment. Prostatectomy is the operation favored by Wallace.

6. **Ano-rectal Ulceration.**—This is the term applied by Wallis to a condition constantly found in the lining membrane of that part of the bowel which lies between the anus and the internal sphincter. This condition Wallis believes to be the initial cause of many of the ordinary rectal ailments, of genuine pruritus ani, fissure in ano, fistula, and also many of those distressing cases of infected ulceration of the rectum, commonly ascribed to syphilis. The lining membrane of the proctodeum is neither skin nor mucous membrane; hence any lesion occurring in this area has a small chance of recovery, (1) because of the scanty blood supply, (2) because of the constantly altering dimensions, and (3) because of the contents of the intestine which are constantly passing over it. Although these abrasions not infrequently occur at two or three different places, the commonest situation is just to one side or the other of the dorsal mid-line. They become covered with granulation tissue, and are practically chronic ulcers which exude in irritating secretion causing pruritus ani. The abscesses discussed by Wallis are the subcutaneous, submucous, ischiorectal, and pelvirectal. He advises opening the ischiorectal abscess outside the sphincter, making one common cavity of existing pockets, draining by a tube through a free skin incision, but not dividing the external sphincter. When the abscess is of the submucous variety, he dilates the opening, passes a hooked director through it and incises the skin over this, dividing everything lying above the director. Thus the external sphincter is divided and the abscess cavity can be thoroughly explored and treated, without materially damaging the mucous membrane. The same method should be adopted in the treatment of pelvirectal abscesses, care being taken not to interfere with the internal sphincter, the levator ani muscles or the mucous membrane. Infective proctitis is treated as follows: The bowels are thoroughly emptied, and at the same time some form of intestinal antiseptic is given by the mouth. The rectum is washed out daily with some antiseptic solution for a week or more, the patient being kept in bed. As soon as the patient's condition permits, the affected bowel is completely excised, and the healthy gut brought down and stitched to the anal margin.

7. **Foreign Bodies in Stomach.**—Following the amputation of a thumb, the patient in question, a woman, aged 30, became very much depressed in spirits, but did her housework as usual. Finally, she began to complain of pain above and to the left of the umbilicus, where a very tender, rounded swelling was evident. The tumor became more pronounced day by day and there was some fever. Alarmed at the suggestion of an operation, the patient confessed that for three weeks she had been swallowing various articles with suicidal intent. A small abscess had developed in the left rectus sheath, and on opening the abscess it was found to communicate directly with the stomach. This opening was enlarged, and by means of a blunt-dressing forceps MacLeod removed a large number of hairpins, sewing and darning needles, safety pins, horse-shoe nails, and ordinary nails, tacks, screws, pins, coins, fragments of glass, chalk, etc. The patient died of exhaustion six days after the operation.

11. **Cultivation of Smallpox and the Vaccinia Parasites In Vitro.**—DeKorte found that the parasites of smallpox and vaccinia will grow and multiply in pure culture in the vitreous humor of the rabbit's eye which is obtained in a sterile condition by [illegible] the eye of a freshly killed rabbit with a [illegible] syringe. Care should be exercised in the operation to procure the medium in a clear condition. It is also advisable to collect it in a vessel in which it can be centrifugalized, the object being to free it from any cellular element which might obscure the issue. The clear supernatant fluid is pipetted off and distributed in small tubes, capped with rubber sheeting to prevent subsequent evaporation. This sterile medium is inoculated with a fair quantity of the infected material which has previously been ascertained by subculture in gelatin and broth to be free from contaminating organisms.

Journal Royal Army Medical Corps, London.

September.

20 Additional Plea for the Recruit. E. Fairland.

12. **Mediterranean Fever.**—Horrocks adduces experimental evidence to show that the *Micrococcus melitensis* when present in dry dust is capable of being absorbed by monkeys. The path of absorption may be through the nares, throat, respiratory passages, and alimentary canal. When present in food it is also taken into the system of monkeys; here, again, the path of absorption may be through the throat as well as through the mucous membrane of the alimentary canal. When transmitted through an unbroken mucous membrane the process of absorption is comparatively slow, and under these conditions the wave of fever appears to be prolonged. The long and variable incubation period observed in monkeys infected through an unbroken mucous membrane is frequently observed in man infected under natural conditions. When the *Micrococcus melitensis* is absorbed through a crack in a mucous membrane or in the skin, or is injected subcutaneously, the absorption is rapid, and the incubation period in monkeys varies from five to seven days. The curve of fever is characterized by a rapid rise usually followed by a rapid fall. These acute infections have also been observed in man infected under the same conditions, but the period of incubation appears to be longer in man than in the monkey. Healthy monkeys may become infected by urine secreted by monkeys suffering from Mediterranean fever, just as in the case of man; the *M. melitensis* is excreted in the urine of infected monkeys. And it seems probable that healthy monkeys walking in the infected secretion convey that specific microbe into the mouth by means of the paws. Infection by means of urine excreted by patients with Mediterranean fever readily explains the cases of Mediterranean fever which appear to rise spontaneously in hospitals. In the absence of specific knowledge as to the mode of excretion of the *M. melitensis* from the human body, sufficient care has not been taken hitherto to sterilize bedpans, urine bottles and sheets soiled by these patients. There is no evidence that Mediterranean fever can be contracted by contact with cutaneous surfaces uncontaminated by urine.

14. **Goats and Mediterranean Fever.**—Horrock's investigations on goats as a means of propagation of Mediterranean fever show that some of the goats in every herd examined were suffering from that disease. The *M. melitensis* is exuded in the milk in enormous numbers when the disease has been present sufficiently long to cause a change in the physical character of the fluid. It is also excreted in considerable numbers even when the animals are in "full milk," and no changes have occurred in either the physical or chemical characters of the milk. The *M. melitensis* is also excreted in the urine of

goats suffering from Mediterranean fever, but up to the present it has only been found when the disease has existed for some time and physical changes have occurred in the milk.

19. **Value of Copper for Purifying Drinking Water.**—According to Fowler, a contaminated water standing for twenty hours in a copper vessel, even though containing a large quantity of copper foil, is not rendered safe for consumption. The time limit of twenty hours is the very extreme one for such a process to be of any practical value, as the water treated one day should be available for use early the next morning. Copper sulphate will act as a fairly efficient germicide of intestinal organisms in twenty-four hours up to 1 part per 60,000 parts with a clear water; up to 1 part per 30,000 parts with a somewhat turbid water, and up to 1 part per 10,000 parts with a foul water. Copper sulphate at 1 part per 10,000 can not be tasted, but it gives a bluish opalescence to the water; at 1 part per 30,000 there is a faint turbidity and a slight trace of blue coloration; at 1 part per 60,000 there is a very slight turbidity, but no blue color. Copper sulphate at 1 part per 60,000 parts of water is just over 1 grain per gallon, and it is a question whether the consumption of such an amount might not have some harmful effect on the consumer. If a man drinks 2 pints a day, he would seem to be taking one-fourth of a grain of the copper sulphate daily. The dose as an astringent is from one-half to 2 grains (B. P.)

21. **Lumbar Puncture in the Newly Born.**—Devraigne relates that he has been long impressed with the constancy of meningeal hemorrhage in cases of cyanosis, convulsions, coma, stiffness of the neck, temperature and contractions occurring in a new-born, apparently asphyxiated infant. Lumbar puncture in such cases reveals the hemorrhage and the hopelessness of attempts to revive the child in the severer cases. Experience has demonstrated that lumbar puncture has been able to effect a cure in certain cases of meningeal hemorrhage in the adult, and he became convinced that it might be applicable likewise for the same condition in the newly born. In May, 1904, a child, after forceps delivery, presented the classical syndrome of meningeal hemorrhage, and about 3 c.c. of bloody fluid was withdrawn by lumbar puncture. The child improved almost at once, and a second puncture two days later showed merely a pinkish fluid. The improvement continued, and a third puncture was made the seventh day after birth, and the fluid was scarcely tinted. The child was cured. Several other infants have been treated in the same way with equally favorable results. In another case the fluid was almost entirely blood, and the unfavorable prognosis was confirmed by the death of the child the next day, when, as surmised, a very large hemorrhage was found. The puncture is made in the same way as in adults, but the needle should carry a wire, as it is liable to become obstructed. The needle should not be inserted for more than from 10 to 15 mm., and Bonnaire says not more than from 10 to 12 mm. The amount withdrawn should not be over 10 c.c., and he never took more than from 3 to 6 c.c. The withdrawal of the fluid reduces the pressure on the nerve centers, the diffused blood possibly acting, besides, as a toxin in the submeningeal space.

22. **Distension of the Heart and Angina Pectoris.**—Tessier thinks that mere distension of the heart may sometimes be the cause of an attack of angina pectoris. He draws a sharp distinction between distension and dilatation and outlines the treatment indicated by the former condition. The heart should be spared all but the minimum of work, and it should be stimulated. The main causes of distension of the heart are sudden aortic insufficiency and overexertion.

23. **Injections of Sea Water.**—Simon and Trousseau have given a fair trial to the therapeutic application of injections of sea water which some observers have recently lauded. In five children with tuberculosis, the injections not only failed to display any beneficial action, but rather seemed to aggravate the course of the disease. In another group of nontuberculous children, no benefit was apparent. There was generally a temperature reaction.

24. **Recovery After Removal of Large Aneurism in the Thigh.**—The sac was not entirely removed, but all the veins and arteries were ligated, not omitting a single collateral. The aneurism had developed in consequence of a bullet wound, and the patient recovered without gangrene or disturbances of any kind. Latour gave him a certificate which released him from military service, as he feared that a long march might bring on trouble again.

25. **Infant Consultations.**—Bué describes how to install a special service for healthy infants. All the mothers delivered in his maternity are urged to bring their babes back for consultation once a week at a certain hour. Records are kept of each child's weight and general condition from week to week, and if there is any interruption in normal growth the causes are sought and remedied. The education of the mothers in hygiene and in the care of their children has been of incalculable value, and the pride of the mothers as they present their healthy little ones and compare them with others has been an important factor in the fine results attained. These "consultations" are now installed in a number of French, German and Spanish cities since Budin first originated them in 1892. The advantage to young physicians to study the normal child's development is not one of the least of the benefits of the plan. Most of the "consultations" now have a milk delivery station attached, and to this feature the "consultations" owe their popular name of the *Goutte de Lait* (Drop of Milk). Only three things are necessary to install one of these, namely, scales to weigh the infants, an apparatus for sterilizing the milk, and the devoted services of some physician. The community generally donates the room or three rooms required and the expense of installment, but if sufficient funds are not realized in this way private benevolence must be solicited. The daily press will usually respond to an appeal for this philanthropic purpose. The waiting room requires merely benches, the weighing room has a table with the scales and another table for the assistants to write on, and the third room is the milk sterilizing and supply department. A record of each child is kept in a large ledger, with the details of its weight, health, etc., at each visit, and a card is given each mother each week on which is recorded the weight of the child, and whether nursing or bottle fed, and the amount of milk it is taking, this card to be presented with the child at each consultation. In the industrial centers the consultations are held on Sundays. The mothers are warned not to bring the children to these consultations if they seem sick, and each child as it arrives is hastily examined and turned away if not apparently healthy. After all the children have been weighed and registered, in turn, in the presence of the mother, the physician makes a short address to the assembled mothers, using one of the infants for a demonstration. In one town in France the mortality has fallen from 17.5 to 2.28 per cent. among the infants brought to these consultations.

27. **The Laboratory on the Summit of Mont Blanc.**—In 1893 Janssen witnessed the completion of the laboratory built on the ice at the top of Mont Blanc and was able to confirm his previous assumption that the oxygen lines in the spectrum are of telluric origin and that there is no oxygen in the sun's

actual spectrum. Switzerland now has three such laboratories, the one on Mont Rosa, where Mosso works, and Vallot's observatory, lower down on Mont Blanc. Valuable contributions to our knowledge of physiology may be expected from these elevated laboratories, but, as Bayeux remarks, a robust physique, besides scientific ardor, is required for physiologic research at these altitudes. Many are called, but few are chosen.

31. **Treatment of Infants of Tardy Growth.**—Terrien discusses the indications for buttermilk, malt soup, and Mery's vegetable soup for the feeding of children who are not developing normally, or who have just passed through an acute gastrointestinal affection. The buttermilk is slowly heated to the boiling point after addition of a tablespoonful of rice, arrowroot or oatmeal, and allowed to boil up three times, constantly stirring, then set aside to cool. The buttermilk contains large proportions of lactic acid, sugar and starch, with very little fat.

33. **Diet in Epilepsy.**—Good general hygiene and avoidance of digestive disturbances are sufficient, without any special dieting, in epilepsy, according to Voisin.

34. **Haffkine's Anticholera and Antiplague Vaccination.**—Lew concludes from the history of Haffkine's work in India that his method of vaccination renders contagion of plague three times less probable than without it, and a fatal termination two times less probable, that is, it reduces the chances of death to one-sixth of the non-vaccinated subjects. His anticholera vaccination has now established itself on such a footing that its results are no longer published any more than those of vaccination against smallpox.

35. **Bacteriology of Fibrinous Inflammations of Air Passages.**—Gerber found diphtheria bacilli in more than three-fourths of his 40 cases of fibrinous rhinitis. There were no general symptoms or fever in about three-fourths of all the cases, including those with and those without diphtheria bacilli. The proportion was less in the fibrinous throat affections, not more than half of 127 patients with fibrinous pharyngitis presenting the diphtheria bacilli. He advises therapeutic injections whenever the general symptoms are severe, even when bacteriologic examinations are negative, but, on the other hand, does not advise them even when diphtheria bacilli are found if the clinical manifestations are insignificant.

41. **Atypical Myeloid Leukemia.**—Hirschfeld draws the composite picture of acute myeloid leukemia from 8 cases in the literature, and that of chronic atypical myeloid leukemia from 12 cases. He then reports a case of myeloid leukemia, personally observed, in which the blood findings were at first typical, but gradually became atypical, as he describes in detail.

42. **Test for Acetone.**—Frommer alkalinizes the urine with potassium hydrate and then adds a few drops of a 10 per cent. alcoholic solution of salicyl aldehyd (1 salicyl + 10 alcohol absol.) and heats to 70 C. (158 F.) In the presence of acetone a purple ring forms at the junction of the two fluids.

43. **Pathogenesis of Tuberculosis.**—Weleminsky has been making an extensive study of the behavior of the regional lymph glands in respect to organs infected with tuberculosis. He has found that when the tubercle bacillus has been at work for a certain length of time in a region the lymph passages are no longer susceptible of being infected. Infection then spreads by way of the blood or by contiguity. Spontaneous infection of man is always lymphogenic. Putting these facts together has convinced him that man becomes infected with tuberculosis from without only once during his lifetime, the same as in syphilis and in other chronic infectious diseases. Almost every case of spontaneous tuberculosis in man and animals is a primary affection of the lymphatic system.

45. **Intestinal Concrements.**—Naunyn relates that a peasant of 40 suddenly exhibited symptoms of ileus, and after extensive irrigation of the bowels passed fifty cherry stones. Ten or eleven months had passed since he had eaten the cherries. Naunyn reviews the present status of our knowledge of intestinal concrements and then describes the case of a young physician who had used for ten years a mouth wash of tincture of myrrh and ratanhia to relieve a painful gingivitis. He used the wash several times a day, especially before meals. The particles of resin in the mouth wash collected in the digestive tract and caused symptoms suggesting recurring appendicitis or perityphlitis, when, in fact, the trouble was merely irritation of the mucosa from the rubbing of the conglomerations of resin. These accumulated at the sigmoid flexure and sometimes caused slight fever, but the symptoms were always comparatively mild. The disturbances were cured by dieting to insure soft stools with as little development of gas as possible. Every development of gas is liable to entail great disturbances. This explains the severe trouble after apparently insignificant errors in diet. The case was puzzling until the discovery of the lumps in the stools, and the chemical tests revealed the presence of resin, when the patient, on inquiry, told of his mouth wash.

46. **Resonance in Area of Dullness in Effusions in the Thorax.**—Bäumler calls attention to a peculiar tympanitic,

resonant area inside the limits of the dullness from accumulations of fluid or pus and air in the thorax. He has noticed it in several cases, and here describes in detail five of them. The underlying conditions were different in each, but all presented this resonant area in the midst of the area of dullness. In one it was due to a compressed strip of lung tissue adherent to the thoracic wall, in others to accumulations of air in masses of fibrin left from preceding inflammation. He gives illustrations of five cases, with postmortem findings in four. One patient recovered after treatment for pneumothorax, followed by large serous effusion. The area of resonance in this case was at the right, low down, near the spine, but it changed more to the front and became higher if the patient lay on his left side. The depth to which the exploratory needle is inserted should be measured in such a case. The relics left of the pneumothorax above probably caused the resonance which was transmitted through the fluid below.

48. **Cure of Tuberculous Pneumothorax.**—Penzoldt is able to report the cure of a patient with tuberculous pneumopyothorax with tuberculosis of the lung, with no recurrence during nearly five years since. Treatment consisted of the strictest rest and open-air reclining, with abundant nourishment. For eleven months this was enforced, the patient, a physician of 30, living in this way on a veranda and never leaving the floor during this period. He did not resume his work in the laboratory for two years and did not take up his full work until after three years. The fever gradually subsided during the first month, and in two months afterward a large effusion had collected in the place of the pneumothorax, containing pus cells, but not causing fever after the first month. The local treatment was by repeated punctures, followed by injections of iodoform. Notwithstanding the compression by air and fluid for nine months at least, the lung did not seem to have lost its elasticity, but resumed its functions when the compression was removed. Tubercle bacilli were found alone in the puncture fluid. The first symptoms of a tuberculous affection had been noticed about a year before the pneumothorax developed. Nearly a year elapsed before the patient was allowed to go up or down stairs, and more than a year before he was allowed a short stroll in the garden. The rest and repose are considered by Penzoldt as perhaps the most essential factors in the treatment. In two apparently similar cases this treatment failed to arrest the progress of the tuberculous affection. If there is a possibility that the aggravation of the case is due merely to the pyothorax, then the Bulau, Pichler or Perthes' procedures might be tried. In case pus cocci are found in the effusion, and the trouble seems to be merely a pyothorax in a tuberculous person, if the general health allows and the lesion is unilateral, radical intervention is justified and may insure good results. If tuberculous patients were content to continue the open-air reclining and taking an abundance of nourishing food long enough, better results would certainly be chronicled in many cases. Above all things, they should not allow themselves to be deluded into relaxing their absolute rest mode of life when improvement begins to become manifest. Physical rest is imperative for months and years.

49. **Treatment of Epilepsy.**—Strümpell remarks that the majority of his epileptic patients have already been treated for years by other physicians before they come to him, and have taken quantities of the bromids without apparent benefit. His experience has convinced him that, as a rule, the symptomatic results of this drug have been overestimated, while its injurious by-effects have been underestimated. In a recent case he does not give the bromids nor in cases in which the intervals are two or three months or longer. When the attacks are very frequent he gives bromin, but very cautiously, watching for its general as well as for its symptomatic effect. The mental decline which some accept as the inevitable result of the epilepsy in certain cases, he thinks is much more liable to be due to chronic bromin intoxication. In place of bromin he gives belladonna and zinc oxid. They have sometimes succeeded after failure of bromin; especially in petit mal the latter has rendered him good service at times. An infusion of valerian, particularly before retiring, has also been found beneficial by some patients. In discussing the subject of exercise for epileptics, he states that one of his patients took a mountain pedestrian tour and afterward felt better than for years. He emphasizes the fact that the epilepsy is only a symptom, and that the general and psychic condition must be studied as much as this one symptom. He suggests that possibly the epileptic seizure may be a sudden discharge of all the accumulated tonicity ("spannkräfte") in the motor centers. This suggests further the possibility that it might be possible to prevent the seizures by calling on and fatiguing the motor centers until there is no possibility for their tonicity to accumulate. Treatment by muscular exercise certainly has some theoretic grounds, and he is now ordering therapeutic gymnastic exercises for some of his patients. If the cramps occur specially in a certain limb, he has the patient exercise the groups of muscles involved. He has no special successes to report from this exercise-therapy, and it should always be strictly individualized, absolute rest being indicated for some patients.

55. **Laparotomy in Tuberculous Peritonitis.**—Göschel's experience harmonizes with Wunderlich's in that about 23.3 per cent. of the cases of tuberculous peritonitis with exudation and in 9.8 per cent. of the cases with adhesions the patients can be permanently cured by operative intervention. The laparotomy does not cure the disease, but it creates much better conditions for the spontaneous healing of the lesions. Children recover spontaneously in about a third of the milder, uncomplicated cases. Between 1894 and 1904 Goschel operated on 19 patients with tuberculous peritonitis, the ages ranging from 16 to 56. In three patients the intestines were affected, and the lungs were tuberculous in all but seven. Three of the patients were completely cured, the interval of good health being from six to eleven years. A number of others were materially improved; the rest succumbed to the progress of the disease or its localizations elsewhere than in the peritoneum. The details of a number of the cases are given, with the admonition that laparotomy always helps, sometimes cures and never harms.

56. **Essential Albuminuria.**—Neukirch's daughter, when about 10, had an attack of diphtheria, and afterward for years passed alternately normal and albuminuric urine. The transition from normal to albuminuric urine was sudden and liable to occur at any time. The albuminuria finally vanished altogether in about five years, after a sojourn among the mountains, and there has been no sign of nephritis at any time. The patient has been in perfect health for eight years. By exclusions he has come to the conclusion that the albuminuria must have been the result of some disturbance in the innervation of the kidney.

58. **Gastroenterostomy in Treatment of Non-cancerous Stenosis of Pylorus.**—Fraenkel relates the details of 13 cases and the results of recent examination of the 9 cured patients. The outcome of the latter is extremely gratifying and should compel an earlier resort to intervention in such cases without postponing it so long that the patient succumbs to starvation or to the result of repeated hemorrhages as in the four fatalities in his experience.

59. **Cure of Spondylitic Paraplegia.**—Schilling comments on the fine results that can be attained in the treatment of spinal affections when the physiologist, the neurologist and the surgeon work together for this end. In a case described, the symptoms suggested spastic, atactic paraparesis at first, but a tuberculous apical affection and the prominence later of the fifth dorsal vertebra confirmed the diagnosis of spondylitic paraplegia. The patient was treated with the *Rauchfuss* method of suspension, with the result of a complete cure in two and a half years. He recommends this hammock-like appliance as desirable to prevent decubitus in the bedridden.

60. **Symmetric Proliferation of Fat Tissue.**—Koch attributes the symmetric lipomatosis in the case under observation to a fall from a scaffolding three years previously. The patient fell on his feet and the spine has been sensitive ever since. There was symmetric weakness in the arms and they grew very fat in parts, with great weakness. The weakness in the arms was not noticed until about a year after the accident, but then became so severe that the man was unable

work. The proliferation of fat accompanying the motor weakness of the musculature is corroborative of the spinal origin of the trouble.

61. **Hourglass Stomach.**—The hourglass stomach in the case reported by Goldschmidt was evidently congenital, and had caused no symptoms until hemorrhage occurred in a small ulcer in the pylorus region. The blood filled the cardial part of the stomach which protruded in the right half of the hypochondrium, and was supposed at first to be the tumefied spleen. There was no vomiting and the stools were normal.

62. **Treatment of Pleuritis with Effusion in Course of Pulmonary Tuberculosis.**—Doerfler noticed long ago that progressing cases of pulmonary tuberculosis seemed to be favorably influenced by an intercurrent pleuritic effusion on the same side when the latter was removed by thoracentesis after it had lasted about a week. His experience since has effectually confirmed this observation, and he states that of 45 patients with pleuritis with effusion accompanying pulmonary tuberculosis, treated by thoracentesis, only 5 failed to derive great benefit from it. He explains this benefit as due to the hyperemia which follows the removal of the effusion. The action of the intervention is similar to that of a laparotomy in tuberculous peritonitis. Doerfler waits a week to allow the lung to be well compressed by the effusion, and then evacuates it as completely as possible. The beneficial effect observed has led him to ask whether it might not be possible to accomplish the desired end without waiting for intercurrent pleurisy to develop. He refers to Murphy's work in this line. As every case of pleuritis with effusion is suspicious of tuberculosis, the effusion should not be left for more than a week. He adds that it might be well to experiment on animals as to whether an artificial hydrothorax and its removal at the proper time might not help to cure a tuberculous process in the lungs.

64. **Olive Oil in Affections of Stomach and Duodenum.**—Merkel reviews his very favorable experience with olive oil in cases of stenosis of the pylorus with hyperacidity consecutive to an ulcer, also chronic ulcers with hyperacidity, and of hyperacidity with pyrosis, and cases of uncomplicated ulcer. The effect was magical in one case of ulcer, and the patients all gained in weight and strength.

67. **Genesis of Tuberculosis of Female Genitals.**—Merkel describes a case of tuberculous ulceration of the vagina in a woman who had pulmonary tuberculosis and had been in an asylum for five years on account of progressive paralysis. He is inclined to attribute the fresh tuberculous process in the vagina to infection from the woman's sputum-soiled fingers.

68. **Congenital Coxa Vara.**—Hoffa shows by Roentgen pictures that there is a sharp distinction between the congenital and the traumatic or rachitic coxa vara. He thinks the former is the result of some arrest of growth during intrauterine existence, probably due to some affection of the bone. He has encountered six unilateral and five bilateral cases.

71. **Operative Treatment of Tumors in Female Breast.**—Braatz urges the removal of every lump in the breast, even when positively benign, as it may become cancerous later. The benign tumors he cuts out with the scissors under local anesthesia, keeping close to the tumor. General anesthesia is imperative for cancerous growths. For several reasons he urges that an ulcerating cancer should be kept covered tight. Sometimes the growth will heal over under a zinc vaselin dressing. He comments on the way in which a woman with an ulcerating cancer will finger the growth and then shake hands with friends and handle articles in constant use in the family. He does not advise an operation for far advanced carcinoma in elderly women, but insists on the protecting dressing. In removing a cancerous growth, he removes both pectoral muscles with it. Functional disturbances from loss of these muscles are readily prevented by certain exercises which he describes. In order to have complete oversight over the axilla, he carries the incision back to the margin of the latissimus dorsi and makes another, perpendicular incision extending upward to the junction of the middle and outer thirds of the clavicle.

73. **Pathogenesis of Chronic Gastric Ulcer.**—Bloch believes that the reason why ulcers develop more frequently near the pylorus is because this part of the stomach is not subject to such contraction as the greater curvature. When the walls contract over a lesion it is more apt to heal than when it is left open, exposed to the action of the gastric juice. The primary lesion must be often a slight necrosis from some small hemorrhage. This loosens the epithelium and leads to the necrosis, and this, in time, if unprotected, leads to erosion from the gastric juice and ulceration. Attempts to produce a gastric ulcer were successful only when they included some injury to the nerves.

75. **Typhoid Bacilli in Bile of Typhoid Patients.**—Recent experiences by Forster and Kayser indicate that the gall bladder is the lurking place of typhoid bacilli, both in man and in animals. The bacilli linger here and propagate, and are frequently found years after the typhoid fever when attention is attracted to the gall bladder by lithiasis. The cases in which bacilli are eliminated in the feces occasionally in persons apparently healthy, is explained by the finding of these nests of bacilli in the gall bladder. As they are eliminated in the bile, the fact that they do not cause disease may be explained by assuming that the course of the digestive tract below the gall bladder does not contain any portals of entry for these germs. This is an argument in favor of the tonsillar etiology of typhoid. Or it may be that the intestinal tract may have acquired a local active immunity. It is possible also that after subsidence of the irritation in the gall bladder the typhoid germs may die out—an argument in favor of surgical removal of gallstones in such cases. In the cadaver of a woman of 84 who had succumbed to pneumonia, the gall bladder was found chronically inflamed and full of

stones. A few cultures of the colon bacillus developed from .05 c.c. of bile, with innumerable typhoid bacilli. Nothing was known of typhoid in her previous history. In another case, paratyphoid bacilli were found in pure cultures in the bile of a woman of 74 with cholelithiasis. No symptoms of the latter and no history of typhoid had been known during life. In the case of a woman of 40 there have been severe attacks of gallstones yearly for several years. The patient is otherwise healthy, although with a history of typhoid at 10. Typhoid bacilli are found intermittently in the stools and the agglutination test is positive at 1/1,000, macroscopic in three hours. In another case, a woman of 64 had an attack of typhoid fever and typhoid cholangitis. Since then typhoid bacilli are found intermittently in the stools and agglutination is positive at 1/1000. There have been occasional gallstone attacks since the first. Only one of the five cases described occurred in a man. Typhoid bacilli were found in the gall bladder and evidences of cholecystitis, although he had not presented any appreciable symptoms of cholelithiasis. The year before his death he had passed through a mild febrile affection suspiciously like typhoid. In regard to treatment to expel the bacilli from the system, the prospects of immunization processes do not seem very promising, but treatment of the gall bladder seems to offer a chance for success. By doing away with the residual bile the conditions become much less favorable for the growth of the bacilli, and by inducing a copious secretion of bile the germs are liable to be entirely washed away. Surgical intervention might also be considered in case of chronic "bacilli bearers," as this would suppress the focus.

77. **Spirochetes in the Blood of Syphilitics.**—The spirochetes were found in the blood of a number of cases of secondary untreated syphilis. About 1 c.c. of blood was mixed with ten times as much 0.3 per cent. acetic acid. The blood thus dissolved was centrifuged and the Giemsa stain applied. The preceding acetic acid does not interfere with the action of the stain if the specimens are left in it for several hours.

78. **Suprapubic Total Prostatectomy.**—Rebentisch describes four cases of retention from hypertrophied prostate in extremely decrepit men treated with brilliant results by suprapubic removal of the entire prostate. He reviews the history of this intervention and describes the Freyer technic which he follows. It allows complete oversight of the bladder, and is the operation to be selected in case of large tumors and for those in which preceding catheterization is impossible for any reason, or in which the diagnosis is still vague after exhausting all known methods of research. Small, hard, fibrous tumors can be readily removed by way of the perineum, and this route is also to be preferred in case of contracted bladder. In all other cases the choice of the route may depend on the operator's personal preference.

81. **Correction of Abnormally Large Noses.**—Joseph has had considerable experience with operations to reduce the size of unduly large noses. His illustrations show the fine results attained without leaving a trace of a scar. The intranasal technic which he has finally perfected consists of an incision parallel with the edge of the nostril, at the point where the new edge is to be made. He then resects on both sides the median portion of the cartilage framework and sometimes part of the lateral segment of the alar cartilage. The skin of the septum is so elastic that it adapts itself to the altered shape of the nose, not requiring excision. It is sutured with a few delicate stitches to the quadrangular cartilage. By this technic there is not a trace of a scar, either on the external nose nor in the septum. Another improvement in his technic is the substitution of local for general anesthesia. He finds a mixture of adrenalin and cocain sufficient for the purpose. His experience with 100 operations of the kind has shown that this technic is entirely free from danger; the after-treatment requires only a week or two. Some of his patients were actors and actresses whose homely noses interfered with their obtaining engagements. The results have been exceedingly satisfactory in every instance.

83. **Determination of Stomach Acidity.**—Leo replies to criticisms that have been made in regard to his technic for determining the acidity of the stomach content and reaffirms its accuracy and reliability. It shows the total acidity, both the free HCl and that in combination with albuminoids, including the albumoses and the peptones. The total acidity is represented by the amount of $CaCO_3$ necessary to neutralize it. The acidity of the remaining acid residue after neutralization with $CaCO_3$ is due to the biphosphates and the albuminoids, exclusive of the true peptones.

84. **Cytotoxins.**—Lüdke concludes his extensive study of the subject of specific cell toxins and antisera with the statement that to date the action of the various cell toxins is confusing. They intermingle and the products resulting from their action serve further to confuse the resulting picture. The specific action of the cell toxins must be rendered more intense and more specific before satisfactory results can be attained with them.

85. **The Bicycle and the Heart.**—Beyer's investigation of the influence of bicycling on the heart has convinced him that the bicycle has a specifically injurious action on that organ. The heart in the young is particularly subject to this deleterious influence on account of the unfavorable conditions of the blood pressure in youth. Hypertrophy of the heart and nervous heart disturbances are the typical bicyclers' affections. It has been found in Germany that the number of cases of acute articular rheumatism among the recruits has materially diminished of late years, while the number of heart affections has tripled. In one army corps, out of 233 recruits with various heart affections, 41 had been bicyclers, as also 9 of the 18 patients with hypertrophy of the heart, and 8 out of the 37 patients with nervous irregularity in the heart action. In another corps, the proportion was 37.5 per cent. in 293 cases of heart affections, with 23 out of the 52 cases of hypertrophy and 9 out of the 22 of nervous irregularity. He found further that among these recruits those who had previously led a sedentary life formed the largest contingent of heart affections among bicyclers. On Sundays and holidays they took long bicycle trips with overexertion of the heart. Next in number were the workmen who rode the bicycle to and from work. The exertion after the fatigue of the day's work caused overexertion of the heart. The recruiting officers attribute the increase in heart disease among the young men to the lesser hardiness of youth in our day and to the epidemic of influenza. Beyer suggests that unwise or immoderate bicycle riding is a third and no less important factor.

86. **Physicians in Political Life.**—Kühn remarks that medical men take less part in political life than the members of other professions, as a busy physician has little opportunity to mix in public affairs. He reviews the conditions in various countries in this respect. France has invariably taken the lead, physicians always being numerous in her legislature. Cornil and several others are now in the senate, and there are 60 medical men in the house of deputies. When Combes was prime minister there were three physicians in the cabinet. In Italy, prominent medical men are sometimes appointed to the cabinet; Bianchi and Baccelli have thus had cabinet positions in late years and a few physicians are members of the senate. In Spain, physicians are frequently party leaders, and always have a large representation in the legislature, Dr. C. M. Cortezo having recently been appointed minister of public instruction. This participation of the medical profession in political affairs also prevails in Portugal to a lesser extent. There seems to be little of it in Denmark; only one medical man has been in the legislature for several years. The people there are comparatively well educated, and the members of the overcrowded medical profession are unable to maintain the intellectual supremacy which would make them leaders in political matters. He reviews the conditions in Canada, Australia and in southeastern Europe, drawing the conclusion that it is highly important for the members of the medical profession in every country to unite in a firm organization, and following the principle, "In union there is strength," to make their influence felt on all sides and to have their interests represented, especially in legislative bodies. He adds that he is proud to say that Germany can serve as a shining example to all other lands in this respect. Virchow showed long ago what great benefits

result from such a combination, both in political life and in local affairs. He concludes with the prayer that it may be possible to bring numbers of physicians into the national and state legislatures, and that they may all labor for the rights of the medical profession as zealously as Mugdan, their present representative in the German Reichstag.

88. **Face Presentations.**—In twelve years of experience, von Herff has had 21 face presentations in which he interfered to change the presentation, and 6 of the children were born dead. In another series of 76 cases of face presentation in which no intervention was attempted, all the children were born alive except 4. Fehling's and Bumm's statistics give similar results. All the mothers were dismissed in good health. These results indicate that it is unwise to attempt to change the presentation unless forced to hasten the course of the delivery for other reasons or from fear of rupturing the perineum. The birth should be carefully supervised, listening for the heart sounds, and interfering only when pressing indications arise. In case of forehead presentation, however, an attempt should be made to transform it into occipital presentation or, if this is not possible, into face presentation if any intervention is deemed advisable.

89. **Fructosuria.**—Neubauer has encountered a case of pure fructosuria (levulosuria), in which no sugar except the fructose was eliminated in the urine. He knows of only two similar cases on record. On a diet free from carbohydrates the fructose vanished entirely from the urine. Cases of mixed melituria are not uncommon, and he reviews the differences and analogies between these groups and describes a number of interesting tests and experiments with his patients.

90. **Depression in the Aged.**—Gaupp presents here a careful study of the conditions of depression in 300 cases at Kraepelin's clinic in which the patients were all over 45. He also refers to 51 cases of mania, grouping them all by the various manifestations of the mental affection. Simple and periodical mania was more frequent in men than in women, while the conditions with depression were more frequent in women at this age.

91. **Action of Digitalis on Sound Circulation.**—Fraenkel was able to retard the pulse in sound subjects by administering strophanthus, without any by-effects. There was no increase in the blood pressure. If he prevented the slowing of the pulse by giving atropin, then the blood pressure rose above normal. The slowing of the pulse is thus the factor which prevents the increased blood pressure under the action of digitalis.

92. **Permeability of Alimentary Canal for Bacteria.**—Uffenheimer has been studying the permeability of the gastrointestinal walls of newborn animals. He found that the mucous membrane of guinea-pigs did not allow the passage of anything but tubercle bacilli and antitoxin, but that in rabbits and other animals large amounts of albumin and other substances were absorbed as well as antitoxin, etc. The mucosa of the alimentary canal, therefore, behaves differently in these various species.

93. **Red Light in Scarlet Fever.**—Cnopf's communication was reviewed editorially on page 793.

94. **Hepatostomy.**—Cahen relates that he succeeded in saving a patient with a severe pyemic gallstone affection by making an opening into the gall bladder. More radical intervention was impossible on account of extensive adhesions, cholemia and tendency to hemorrhage. The only choice was between hepatoenterostomy and hepatostomy. On account of the patient's extreme debility he decided on the latter operation, and it seemed to relieve the patient at once from his serious condition. Nine months later he was apparently in perfect health, free from all disturbances, and attending to his daily work as a shoemaker. The canal was hollowed out in the liver tissue with the Paquelin cautery to avoid hemorrhage. Owing to the congestion in such cases, the outflow of bile even from the smaller biliary passages is copious and amply suffices to relieve the liver.

95. **Infant Mortality and Survival of the Fittest.**—Among the other points brought out in Koeppe's study of the lessons to be drawn from the statistics of infant mortality, may be mentioned his statement that a high infant mortality in a given year is always followed by a higher mortality among the surviving children in the second and third years thereafter. The reverse is also true, that the measures which reduce infant mortality serve to strengthen the surviving children so that more pass successfully through the second and third years.

Books Received

TRANSACTIONS OF THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. Vol. XVII. Seventeenth Session Held at Birmingham, Ala., December 13-15, 1904. Edited by W. D. Haggard, M.D. Cloth. Pp. 521. Published by the Association. 1905.

INDEX-CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, UNITED STATES ARMY. Second Series. Vol. X. M—Mnikhovski. Cloth. Pp. 935. Washington: Government Printing Office. 1905.

HANDBOOK OF PHYSIOLOGY. For Students and Practitioners of Medicine. By A. Flint, M.D., LL.D. 247 Illustrations—4 in Colors. Cloth. Pp. 877. Price, $5.00 net. New York: MacMillan Co. 1905.

STATIC, HIGH FREQUENCY, RADIO, PHOTO AND RADIUM THERAPY. By W. H. King, M.D., LL.D. Cloth. Pp. 291. Price, $2.50. New York: Boericke & Runyon. 1905.

ABDOMINAL OPERATIONS. By G. A. Moynihan, M.S., F.R.C.S. Fully Illustrated. Cloth. Pp. 694. Price, $7.00. Philadelphia: W. B. Saunders & Co. 1905.

ATONIA GASTRICA (Abdominal Relaxation), by A. Rose, M.D., and R. C. Kemp. M.D. Cloth. Pp. 203. Price, $1.00 net. New York: Funk & Wagnalls Co., 1905.

PRACTICAL MASSAGE IN TWENTY LESSONS. By H. Nissen. 46 Illustrations. Cloth. Pp. 167. Price, $1.00 net. Philadelphia: F. A. Davis & Co. 1905.

RADIUM AND RADIO-ACTIVITY SUBSTANCES. By C. Baskerville, Ph.D. Cloth. Pp. 164. Price, $1.00. Philadelphia: Williams, Brown & Earle.

CLEFT PALATE AND HARE LIP. By W. A. Lane, M.S., F.R.C.S. Paper. Price, 5 S. Pp. 63. London: Medical Publishing Company. 1905.

NEW PATENTS.

Patents of interest to physicians, etc., recently granted:

797838. Tablet-molding press. James F. Buckley, Ilford, England.
797718. Portable *x*-ray apparatus. Eugene W. Caldwell, New York.
797792 Alkyl-oxy-acetyl urea and making same. Erik C. Clemmensen, and A. H. C. Heitmann, Detroit.
798013. Antiseptic compound. Alphonso M. Clover, Ann Arbor, Mich.
797696. Vaginal syringe. Willis P. Flowers, Scranton, Pa.
797707. Obstetrical pad. Emmeline H. Pearson, Washington, D. C.
797607. Invalid-table. John [illegible]
797644. Pill-tile. Walter E. [illegible]
12384. Re-issue. Apparatus [illegible] Edgar F. Billings, Boston.
798093. Hypodermic syringe. Edward F. Dean, Denver.
798205. Making nitric acid. Heinrich H. Neidenfuhr, Halensee, Germany.
798208. Making sodium ferrocyanid. Camille Petri, Buchsweiler, Germany.
798457. Self galvanic massage apparatus. Sven R. E. Schmidt, St. George, S. I., N. Y.
798367. Obstetrical appliance. Joseph H. F. Smokey, Natchez, Miss.
798464. Support for prolapsed uterus. Lewis G. Sprague, Henderson, N. Y.
798149. Stopper for water bags. Charles O. Towne, Torrington, and J. H. Woodward, Waterbury, Conn.
798239. Apparatus for producing carbonic acid. Gregor Walzel, Newark, N. J.
798893. Breast-pump. Uberto D. Ezell, Kimball, Texas.
798908. Apparatus for carrying out bacterial purification of sewage or drain water. Christoph Kremer, Gross Lichterfelde, near Berlin, Germany.
798611. Surgical appliance. Willard [illegible] Main, Iowa City, Iowa.
798920. Reducing oxalic acid and [illegible] electrolysis. Emil von [illegible], Prag[illegible]
798833. Intermittent movement in [illegible] J. Ruff, Quincy, Ill.
798852. Anesthetic generator and mixer. David D. Weisell, Fort Wayne, Ind.
799216. Syringe. Frank C. Barnes, Fremont, Ohio.
799166. Package for surgical ligatures. Robert W. Johnson. New Brunswick, N. Y.
799272. Medical and surgical vibrator. Harold W. Shonnard, East Orange, N. J.
799114. Speculum. Crispus D. Tracey, Little Rock, Ark.
799702. Operating table. Ashbel P. Barlow, St. Joseph, Mich.
800071. Obstetrical appliance. Richard H. Cheatham, Vermont, Ill.
799895. Massage appliance. John D. Doughty, and J. R. Sanford, Conn.
800087. Chemical apparatus. David Genese, Baltimore.
799568. Ear-trumpet. George G. Lewis, Syracuse, N. Y.
799664. Apparatus for treating ankylosis of the knee. Robert R. Norwood, Mineralwells, Texas.
799806. Nursing bottle. Ernest H. Simonds, Berkeley, Cal.
799881. Massage device. Jerome B. Wells, Cleveland, Ohio.

Address

THE RESPONSIBILITIES OF SURGERY.

CHAIRMAN'S ADDRESS BEFORE THE SECTION ON SURGERY AND ANATOMY, AT THE FIFTY-SIXTH ANNUAL SESSION OF THE AMERICAN MEDICAL ASSOCIATION, *PORTLAND, ORE., JULY 11-14, 1905.*

MAURICE H. RICHARDSON, M.D.
BOSTON.

In this communication I wish, in the first place, to pay a warm tribute to the splendid work that is being done in this country by the surgical profession; and I wish to emphasize particularly the value of the contributions from the country surgeon as distinguished from the metropolitan surgeon. That a populous community is not indispensable for the development of the best and the highest the little town of Rochester, Minn., has most brilliantly demonstrated. The educated, well-balanced, conservative man, considerate of others and of himself, will find in every community abundant opportunities for the highest professional attainments; and he will there make himself a power for good and an honor to his profession.

It has seemed to me, especially in the past few years, as I have been brought in contact with physicians and patients in widely separated communities, that the time has come when we must consider very seriously certain questions concerning the practice of surgery: Who shall practice surgery and who shall not? What preparation shall be required of those who propose to stand before the community as properly qualified surgeons?

The burden of the following remarks is that those only should practice surgery who, by education in the laboratory, in the dissecting room, by the bedside and at the operating table, are qualified, first, to make reasonably correct deductions from subjective and objective signs; secondly, to give sound advice for or against operations; thirdly, to perform operations skillfully and quickly, and, fourthly, to conduct wisely the after-treatment.

As a rule, the community does not appreciate the value of services, whether medical or surgical, because it fails to realize in the least degree the burden of care placed on the physician and on the surgeon. The layman does not always understand that a mistake in diagnosis, an error in judgment, a fault in technic, may mean life or death, health or sickness, strength or disability, joy or sorrow. He can not in the least comprehend the difficulty of avoiding these errors; he does not realize that the *vis medicatrix naturæ*, too little relied on in the past, too much in the present, receives to-day credit which belongs almost wholly to the educated and skillful practitioners of medicine and surgery.

The community is, perhaps, not to be criticized if it fails to estimate properly the value of professional services when it sees problems demanding exercise of the highest skill undertaken by men but little trained to solve them. That the community is sincere can not be denied when the lives and health of its nearest and dearest are submitted to the ignorant, the inexperienced, the unskillful. This shows, perhaps, more than anything else the contempt for thorough education and long training which makes possible the evils of which I speak. On the part of the laity, sound opinion is much to be desired; on the part of the profession, a candid admission of certain serious defects. In matters surgical, however, public opinion is hard to mould, for the reason that the results, on the whole, are good, whatever the operation and whoever the operator. An amputation results in recovery of the patient; the surgeon's skill is manifest to the family and friends, who fail to see that the amputation was, perhaps, unnecessary. A patient dies after a hysterectomy; the community—realizing that the operation is a dangerous one and believing that patients seldom recover from it, unaware that the mortality in skillful hands is not greater than that of childbirth—looks on the result as inevitable.

The consulting surgeon can not but be impressed by the frequency of useless or worse than useless operations. He sees too often the unfortunate results of hastening the patient into operative procedures based on errors in diagnosis and in prognosis. On the other hand, he sometimes sees a patient refused an operation which is called for in the most positive tones.

Perhaps the most common error, as observed by the consulting surgeon, is the failure to detect at the earliest possible moment those internal lesions which demand, as the only chance of recovery, instant operation. The mortality in these cases is the mortality of acute abdominal surgery to-day. Excluding acute abdominal emergencies and cerebral hemorrhage of traumatic origin, the mortality of surgery is trifling. The responsibility of deciding to call the surgeon must rest, of course, first on the family and then on the physician. Too often, however, the necessity of intervention is not recognized even by the surgeon. One seldom sees a newspaper that does not contain an account of the loss of a life which might have been saved by prompt and skillful surgery.

The task before me is a serious criticism of what is going on in every community. I do not single out any community or any man. There is, in my mind, no doubt whatever that surgery is being practiced by those who are incompetent to practice it—by those whose education is imperfect, who lack natural aptitude, whose environment is such that they never can gain that personal experience which alone will really fit them for what surgery means to-day. They are unable to make correct deductions from histories; to predict probable events; to perform operations skillfully; or to manage after-treatment.

The chief source of trouble lies in the ambition—perfectly laudable—which so large a proportion of medical men possess, to become surgeons. The ho pitals in many small communities have on their staffs every medical man of prominence in town, all of whom take alike the medical and the surgical services. The reason for this is that the co-operation of every physician is necessary in order that the hospital may be built. A place on the staff becomes a *sine qua non.*

The truth is that in small places the two or three men best fitted for surgery should be made the surgeons of the place, and to them should be referred all surgical work. With the great development of surgery to-day, it is, indeed, a sparse community which can not support two surgeons. It is, I think, incumbent on these men to give up to the others their medical practice. In this way alone may surgeons become fitted for the responsibilities of surgery in the less populous areas; and in this way they will receive an education and experience which may make them of national or even international reputation.

But may we not depend on a process of natural selection in the development of the surgeon—a survival of the fittest? This process will, no doubt, prove in time effectual, but in the meanwhile hospital positions and other opportunities will remain in the hands of those unable properly to utilize them. We have time and again seen positions held to the age limit by those on whom the great opportunities of a large clinic were almost wholly wasted.

The man who by nature is endowed with the gifts which make him a good practitioner of surgery will not fail to make the best use of those gifts, whatever his environment.

Though the task of criticism that I have before me is a disagreeable one, the time has come when the attention of a representative body like this should be called to what is going on in every community.

Perhaps the least offensive way in which to treat this part of my subject would be by limiting my illustrations, as far as possible, to things which I have seen and done during many years of surgical practice. For if one of ordinary intelligence and education, who has had unusual opportunities to gain experience, is liable to err, how much more liable is he to whom opportunities for study and practice have been wanting. As human frailty precludes the absolute prevention of errors, even in the hands of the experienced, it must follow that in the hands of the inexperienced they will occur in a much larger proportion of cases. Some operators show, in the very beginning of their practice, a skill which can never be attained by others, even after years of operating; but, other things being equal, the better the training the better the results.

As far as my observation goes, the most serious errors have resulted from treating as benign those tumors which were, in reality, malignant. The most costly have resulted from giving too favorable prognoses in acute abdominal diseases. Most of these cases I have reported as they have occurred. Several tumors of the breast I have regarded as simple retention cysts or as fibromata; and the patient, relying on this opinion, has gone away, only to return at the end of a few years with extensive cancer. Cases of this kind have convinced me that the only safe rule in the treatment of tumors of the breast is to regard them all as malignant or as likely to become so. I have at least learned my own fallibility in the diagnosis of lesions of this kind.

On the other hand, there have been many cases that I regarded as malignant which were in reality benign. In one case I agreed with the operator in the diagnosis of a malignant tumor of the femur, only to find after amputation at the hip joint that the growth was not in reality malignant, but a disease of the bone which made it extremely fragile. During the manipulations of the operation the other femur, which was over the end of the table, broke; and the patient was left with but one leg, and that a broken one.

In following up the malignant cases at the Massachusetts General Hospital for ten years I found not a few instances in which the disease had been diagnosticated as hopeless cancer, but in which the patient had recovered entirely either spontaneously or under medical treatment.

In abdominal surgery, the errors in diagnosis have been numerous, and in some instances costly. One frequent source of error is in the diagnosis of pregnancy. The inability to distinguish between a pregnant uterus and other tumors of the abdomen would seem to be inexcusable. As a matter of fact, however, it is at times extremely difficult, if not impossible, to make a distinction. In some cases I have failed to recognize pregnancy, even with the tumor in my hands. Once, after the removal of a large right ovarian tumor, I found what I supposed to be a left ovarian tumor. In trying to tap it—the custom in those days—I discovered that it was a pregnant uterus. The Fates in this case, however, were propitious, for the woman lived and was delivered at full term of a healthy child.

The most prolific source of error in acute disease will be found in the prognosis of acute abdominal infections and other acute abdominal emergencies in which the patient's life depends on the promptness of applying the remedy. I have referred to these errors as costly ones, not because they are in the long run any more fatal than errors of diagnosis, but because they are likely to be so quickly fatal. The postponement of surgical remedies in acute abdominal infections like appendicitis and cholecystitis; in perforations of the alimentary canal; in twists, intussusceptions, hemorrhages and rupture of abscesses—the putting off of explorations on the strength of a faulty prognosis—has been the most disastrous of all.

In the actual performance of the operation, a rigid self-criticism always reveals errors of technic more or less important. Fortunately, technical errors—unless they are essentially irremediable—do not seriously affect the prognosis. From time to time, however, errors purely technical—errors in anatomy or in asepsis—have compromised fatally the result of the procedure. I recall instances in which operations progressing in the most satisfactory manner have suddenly—by the surgeon's failure to recognize and avoid such structures as the ureter, the intestine, the facial nerve or the recurrent laryngeal—placed on him a burden of chagrin, or even remorse, which was, indeed, hard to bear.

To these errors of diagnosis, prognosis, indications, technic and after-treatment, one must add such things as fatal capillary hemorrhage in cases of jaundice; wound infections in which the most rigid review of the case fails to show any technical error; sudden deaths from pulmonary embolism, from intestinal obstruction, from ileus. I have had, too, in my experience, such unusual disasters as the suicide of a patient convalescing from appendicitis, a suicide after gastrostomy for dilatation of the esophagus.

These calamities—which are only a few of the many that beset the patient from the moment the anesthetic is begun until he has fully recovered from the operation.

and even to his dying day—make a list of possibilities so long that in the simplest case one can not but feel the heavy load of responsibility. Even after a perfect convalescence patients have died suddenly. The death may have apparently no connection with the operation. I recall the case of a patient who died four weeks after hysterectomy while being fitted with an abdominal supporter. At the autopsy nothing abnormal could be discovered.

All surgeons are liable to error not only in diagnosis, but in the performance of operations based on the diagnosis. Such errors must always be expected and be included in the contingencies of the practice of medicine and surgery. Doubtless many of my hearers can recall cases of their own in which useless—or worse than useless—operations have been performed. If, however, serious operations are in the hands of men of large experience, such errors will be reduced to a minimum.

In the beginning of abdominal surgery the mortality of the great operations was high, as we all can remember. The individual surgeon, however, soon acquired a skill in technic which rapidly reduced his mortality. The deaths in hysterectomy, for instance, have been reduced from 30 or 40 per cent. to about the mortality of ordinary childbirth. One who has operated in a large number of cases of this kind can predict with considerable certainty the outcome of his case. If, however, we could get the general mortality of hysterectomy to-day, we should find, I fear, that in the community as a whole the mortality is no less than it was in the beginning. This is because men who are not fitted for the responsibilities of this grave operation are willing to accept them. Not only do inexperienced men undertake without hesitation this often formidable procedure, but they advise the operation when it is unnecessary. So it is in many other abdominal operations. I have known a man to open the abdomen for some simple cause, to do damage to the intestine which he could not repair, to close the wound and send the patient to bed, knowing perfectly well that she must die. Such things are hardly conceivable, but they are nevertheless true.

In Europe I once saw a brilliant operator of worldwide reputation remove, with the Fallopian tube, a section of the sigmoid flexure. The blunder was not discovered until the specimen had been removed, but the surgeon knew enough to see his error and to repair it. I once was in such a tangle of adherent and obstructed intestines that I was unable to recognize the distal loop, after separation of the proximal. I was able, however, to extricate my patient from an apparently hopeless situation. Every proposed abdominal operation presents possibilities of error and disaster which are appreciated, feared and provided against in proportion to the operator's experience. *Facilis descensus Averno . . . sed revocare gradum . . . hic labor est.*

In fractures, especially, one sees the evil results of ignorance and inexperience. The expert surgeon devotes much of his time to the correction of deformities and delayed unions. He is pestered by appeals to testify in court in the defense of physicians, even when the treatment of fractures has been good. He can not but feel, however, that much is asked of him when he views some of the cases the treatment of which he is requested to defend. I am not sure that suits for damages against physicians—like suits against corporations—unjust as most of them are, do not tend in the long run to work out problems such as that which I am considering: a strict pecuniary accountability for bad results is often the only argument to which inexperience and overconfidence will yield. The trouble is that the dissatisfied layman, the unscrupulous lawyer, the malignant witness, and the ignorant jury make a combination sufficient to blast the best reputation and wreck the fairest cause.[1]

Surgeons of the greatest skill and experience feel more anxiety in the treatment of fractures than in almost any other form of injury. Few can without humiliation review their results.

The tendency at the present time is and should be toward specialization in the treatment of fractures. In cities, and, in fact, in all communities, it would, I am sure, be an advantage if the treatment of fractures were placed in the hands of men who have a special aptitude for this branch of surgery. The orthopedic surgeon is by his training accustomed to the making and the fitting of apparatus; and the results in fractures depend very largely on the way in which bones are held by apparatus in proper position after once they have been put there. At the Massachusetts General Hospital fractures of the jaws have for many years been referred to the dental school, and fractures of the nose to the department for the nose and throat—much to the advantage of the patient. Would it not therefore be wise if fractures in general were regarded as a branch of orthopedics?

With the great increase in the number of surgical operations, the discontented are beginning to bring actions against physicians for bad results in fields of surgery other than that of fractures. Hence, although malpractice suits are, as I say, not common, yet the number of complaints is greater every year. I have known suits to be brought for various reasons—for alleged negligence in leaving gauze in the wound, for operation without the patient's understanding or consent, for abdominal fistulæ, for burns, for postoperative hernias and the like. In one instance a surgeon was actually sued because he advised against the removal of a uterine fibroid; in another case damages were claimed because a surgeon overlooked a splinter of wood in a boy's neck; in still another, because amputation was performed on a minor without the consent of the father. Suit was brought in one case for pressure sores following the application of plaster of paris.

The cases that come to trial are the ones that we hear of: doubtless many claims for damages are settled out of court. Whether the recent introduction of insurance against claims for damages will increase the number of suits or not, is thus far a matter of opinion. When it becomes generally known that corporations stand by physicians, malpractice suits will, I think, increase, especially if the insurance companies make settlements favorable to themselves, without the consent of the physician. On the other hand, a determined and obstinate defense seems a real protection.

As I have said, the responsibilities of surgery are being brought home to the physician more forcibly by claims for damages than by anything else. Possibly this holding of the physician liable will increase his sense of responsibility to such an extent that he will hesitate to undertake operations for which his educaical school, but he must continue it later at every possible opportunity. The allied sciences—chemistry, bacteriology and the specialties of medicine and surgery—should be a part of his education; but, as I have said, most of his time in practice should be devoted to the study of the healthy living body, the healthy dead body; the pathologic living and the pathologic dead.

---

[1] Almost as I am writing these words, I am asked to defend a physician of whose treatment of a Colles's fracture only two criticisms can be made: one, that the fracture was not reduced under ether; the other, that the arm (in the case of a woman of sixty) was kept in splints too long. Nevertheless, there are permanent deformity, impairment of wrist motion, and stiff fingers. The physician felt confident that he could treat a little thing like a Colles's fracture as well as anybody else, even in a large community, where the standard of skill was high. In consequence, the patient is dissatisfied, the physician worried, and the surgeon annoyed.

In my recent teaching I have made use of the autopsy for the education of the students' touch, especially in abdominal diseases in which the surgeon is frequently obliged to depend on the evidences of his fingers to decide for continuance or abandonment of his operation. The history is read and the case is discussed. The abdominal incision is next made as if for operation. The student is then required to explore the abdominal cavity with his hand, and to record his opinion as to the lesion present and as to the condition of all the abdominal organs. If no disease is diagnosticated beforehand, he is required to give his opinion as to the condition of each organ. To some extent the diagnosis may be made on the pathologic appearances seen at autopsy; but the pathologic appearances during life are so different from those after death that the surgeon who depends exclusively on experience gained at the autopsy table is liable to err.

A thorough knowledge of practical anatomy, such as was insisted on in the preanesthetic days when the success of the operation was largely a matter of speed, should still be insisted on as the first and most important equipment of the operating surgeon. Not that the extraordinary skill and rapidity of some of the operators of those days is essential when anesthesia and asepsis make deliberate and careful dissections possible, yet there is, in my judgment, among even the experienced operators, a deplorable ignorance of normal anatomy. The freedom and rapidity with which cuts are made in close proximity to important structures is to the anatomist appalling. It explains, however, the frequency [illegible] the so-called "accidents" of surgery: urinary and fecal fistulæ, paralyses and hemorrhages. I would advise the surgeon, both in preparation and in active practice, to make use of every opportunity for dissection; to become so familiar with the human body that he can not fail to recognize every structure the moment the smallest portion of it is uncovered; to be able to proceed directly on his operative route without being obliged to halt for a moment to study his landmarks. Normal anatomy is quite as important in operative surgery as pathologic anatomy is in the understanding of disease. Anatomy should be, if not first, a strong second in the education of the surgeon.

The chief preparation of the surgeon, after the acquisition of the knowledge given him in his medical school courses, must be in direct contact with patients. The medical school will have qualified him to observe the normal working of the human body (physiology), the structure of the body (anatomy), the results of disease (pathology as illustrated on the dead). The courses will have given him an opportunity to see, in a very limited number of cases, the pathology of the living (symptoms as expressed at the bedside). He will have learned the theory of repair of wounds—inflammation, suppurations and all the processes which are erroneously spoken of as surgical pathology. In the ordinary courses of study during his four years at the medical school he will have a very limited experience. In order to become a surgeon qualified to bear the responsibilities of our profession, he will require an additional training, and that training must be thorough and prolonged. He must be brought into contact every day with surgical diseases in their clinical manifestations; and he must learn, by the observation of an enormous number of cases, to distinguish between diseases so closely resembling each other that he could only with the greatest difficulty describe the differences in words. It is first on this clinical experience that he must rely, and secondly on the observation during operations of the connection between symptoms previously noted and the lesion actually found. It follows that the best preparation that a man can have for becoming a practical surgeon is in the position of assistant. As a medical student his opportunity for observation is at the clinical work. At a distance, perhaps, or near at hand, as the case may be, he observes the examination of the case and the operation on the patient. In as many instances as possible he is required to take his own history and to make his own examination. If he gets an appointment as assistant in a hospital he has an opportunity of observing patients and studying them as carefully as his time permits, of assisting at operations and there seeing the lesions, of seeing in the autopsy room—in cases in which the result is fatal—the pathologic appearances. This is the best preparation that the medical schools and the hospitals offer. After this a course of study in Europe broadens the student's view and increases his experience.

Is this enough to round out a man's education so that he may assume the responsibility of surgery? This is so much better than the education of most men who practice surgery that one is inclined to answer in the affirmative; but I am considering the best education for the surgeon. I have no hesitation in saying that the proper fitting of a man for surgical practice requires a much longer experience as student and assistant than the most exacting schools demand. A man should serve four, five or six years as assistant to an active surgeon. During this period of preparation, as it were, as much time as possible should be given to observing the work of the masters of surgery throughout the world. Nothing broadens a man like observing the work of others. One should never give up visiting the clinics of the masters, no matter how experienced he may be. A man can not but become narrow in his views and limited in his resources, especially in emergencies, if his work has been confined to his own special clinic. Yet, on the other hand, is there not a danger that one may become a chronic student, an imitator of others, without originality or initiative? I believe that there is. I have seen a man hesitate between the teachings of Paris, Berlin, Vienna and London until he had to be prompted by his house surgeon into an American—at home—every-day successful procedure!

The importance of laboratory work—the so-called research work—in preparing a man to become a surgeon, is great. The necessity or the advisability of continuing in the work of active laboratory research admits of doubt. Certain qualities are essential to make a man a good worker in research. It requires quite different qualities to make a good surgeon. The fields are both infinitely broad; and I doubt whether a man can contribute much of value in the field of original research—in the sense of scientific research in the laboratory—and at the same time accomplish much in the field of practical surgery. The clinical man sees every day opportunities for research; problems arise which are of the greatest interest. It is for him to suggest lines for experimental work, but it is not for him to carry out the actual work itself.

In the larger sense, however, the surgeon is engaged in the work of original research. In the clinical manifestations of disease he alone sees the connection between cause and effect. Suggestions as to treatment, symptomatology, prognosis and operative methods occur to him in the course of his daily work; and practical advance in the treatment of disease comes mainly from the results of his observations at the bedside and at the operating table.

How may it best be brought about that surgery shall be in the hands of those only who are by education and experience best equipped to practice it?

Is it better to limit surgery to those who are given courses of instruction and degrees designed especially for the education of the surgeon, or would it be preferable so to educate public opinion that only those could be called on to practice surgery who were known to be well fitted for it?

The trouble with the latter question is that the public is easily deceived in medical matters. Nevertheless there is, I think, a strong public opinion in favor of the practitioners who are known to be surgeons of skill and experience. It is on this power of discrimination between the evil results and the good, and on the dependence of these results on skill, that we must chiefly rely in creating a sound public and professional opinion in favor of special experience and skill in the advising and in the performance of surgical operations, and in the practice of surgery in general.

A CASE OF SYSTEMIC BLASTOMYCOSIS, WITH BLASTOMYCETES IN THE SPUTUM.

DANIEL N. EISENDRATH, M.D.
AND
OLIVER S. ORMSBY, M.D.
CHICAGO.

Through the efforts of Drs. James Nevins Hyde and Frank Hugh Montgomery and other observers, cutaneous blastomycosis is now generally recognized as an entity. The number of reported cases of systemic blastomycosis being few, it seems justifiable to report more or less fully new cases as they occur, so that by a study of the entire group it will be possible definitely to place the disorder in its proper position in medicine. There are now on record four cases of systemic blastomycosis, in which the causative organism appears identical. These were recorded by Busse and Buschke,[1] Montgomery and Walker,[2] Ormsby and Miller[3] and Cleary.[4] Three of the cases were in Chicago, and two of these occurred in the practice of Drs. Hyde and Montgomery. Another case which closely conforms, and which by some observers is classed here, was that reported by Ophüls and Moffitt[5] of California. In these various cases, similar symptoms were presented before death and similar findings were made postmortem, yet marked differences also occurred. In the various cases, the larynx, trachea, lungs, pleura, myocardium, liver, spleen, pancreas, kidneys, adrenals, mesentery, lymph glands, bones, joints, subcutaneous and cutaneous tissues were the seat of the lesions, the organism being found in all these localities. The microscopic findings in all of these cases were similar, differing chiefly in extent of distribution or destruction. The process often resembled pyemia, multiple abscesses occurring in various organs and tissues of the body. In one case (that of Ormsby and Miller), the usual picture presented in the skin by the chronic, purely cutaneous cases was almost entirely absent, only one lesion possessing this resemblance. In another (that of Cleary), no cutaneous lesions were present. These cases resemble tuberculosis, both clinically and pathologically. This is evident from the findings in the past. The miliary tubercles found in the lungs, liver and elsewhere have a close resemblance to the miliary tubercles of tuberculosis in the same situations; and the chief [illegible] those recording cases in the future [illegible] the presence of tuberculosis.

We are indebted to Dr. M. L. Blatt for aid in procuring material for histologic study, and to Dr. H. L. Wolf, house surgeon at Cook County Hospital, for assistance in the work in this case.

Patient.—Polish laborer, aged 33, married and has two healthy children.

History.—His illness began in February, 1904. He was admitted to Cook County Hospital in February, 1905, and assigned to the service of Dr. Eisendrath. He speaks no English, so a satisfactory history through an interpreter was hard to obtain. It is probable that he has had the usual diseases of childhood. He denies venereal infection; he has been a moderate smoker of cigarettes, and drinks occasionally. His surroundings at home were most insanitary.

Present Illness.—The present disease began in February, 1904. He has given two versions of the beginning. The following was the last and seems most reliable: He states that the first noticeable departure from his usual good health consisted in a feeling of discomfort involving the chest on the right side, extending through from front to back. This lasted for a time, and, in fact, is still present, being better and worse at intervals. In June, four months from the beginning, his first cutaneous lesion appeared. This was located below the left ankle and extended down to the heel, and eventually became a little larger than a dollar. Shortly afterward the other lesions appeared, but it is impossible to tell their exact mode of development. In addition to this area on the left leg, the right leg had several large lesions, also the right and left forearm, and the face, chin and neck, especially on the right side (Fig. 1). About November, 1904, he suffered great muscular weakness, and marked swelling of the feet and ankles occurred. This gradually increased until he was wholly unable to work. He stopped work in December. He stated that with the onset of the original pain he employed a physician for two months and was benefited by the treatment. Something was applied to the skin by the physician which made the skin sore, but this soon healed, and was entirely different from the cutaneous lesions present on his admission to the hospital.

Examination.—On his admission to the hospital in February, 1905, he presented lesions on all the above-mentioned areas, and was very much emaciated, pale, anemic, exceedingly weak and had some elevation of temperature. Marked edema was present in the ankles, feet, face and arms. His nails were clubbed, and moderate inguinal adenopathy was noted.

Cutaneous Lesions: There was present on the left leg, below the ankle, a lesion about the size of a silver dollar. One on the right leg (Fig. 2.), on the lower third, occupying the outer and posterior surface, measured about four by two and one-tion has not fitted him; but until some such restraining influence shall have made itself felt, we shall continue to meet with inexperienced men who think themselves competent to treat not only fractures, but all surgical lesions, including those of the abdominal cavity.

Many physicians send patients for diagnosis and opinion as to the advisability of operation without telling the consultant that they themselves are to perform the operation. The diagnosis is made and the operation perhaps recommended, when it appears that the operation is to be in incompetent hands. A disagreeable duty devolves on the consultant. His advice should be conditional that it be carried out only by the competent. Many operations, like the removal of the vermiform appendix in the period of health, the removal of fibroids which are not seriously offending, the removal of gall-stones that are not causing symptoms, are operations of choice rather than of necessity; they are operations which should never be advised unless they are to be performed by men of the greatest skill. Furthermore, many emergency operations, such as the removal of an inflamed appendix and other operations for lesions which are not necessarily fatal—should be forbidden and the patient left to the chances of spontaneous recovery, if the operation proposed is to be performed by the incompetent.

Then, too, many physicians are so inexperienced in the after-treatment of patients that the result is, from this fact, likely to be less favorable. Unless, for example, the after-treatment of difficult gall-bladder operations is to be in the hands of competent men, the surgeon should be unwilling to operate. In such cases he should insist that the patients put themselves under his personal supervision.

The responsibilities of making the diagnosis, of advising the operation and of performing it, and of the after-treatment are great—much greater than even those who practice surgery exclusively, and who therefore understand the difficulties, realize. Even less impressed by these responsibilities are the patients themselves and their friends. Let us consider the operation of appendectomy in the "interval," for example. How common it is for the lay journals to say that the operation is a simple one—so simple that any physician can easily perform it! The needlessness, the simplicity, the fees of the operation are frequently the subject of their jokes. The operation for appendicitis usually is, as we all know, an operation that is easily and quickly performed, and it is almost always successful. At times, however, it is extremely difficult and dangerous, and at rare intervals fatal. The success may depend on some trivial thing, the importance of which can be realized only by men of the greatest experience. In many mechanical things the ultimate results depend on slight causes acting through a long period of time. The winning crew at the end of four miles succeeds in crossing the line a few feet ahead of the defeated crew because of some trivial thing in which that winning boat is superior to the defeated boat. A record of a thousand successful operations for appendicitis surpasses a record of nine hundred and ninety successful operations because of some slight superiority in technic. It would be practically impossible to say that one method is superior to another, and yet it would be absurd to deny that superior results are owing to the best judgment and the best technic. The time chosen for the operation, the kind of incision, the method of treating the stump, the establishing of drainage, are things apparently of little importance; and yet they make the difference of the ten cases in a thousand; they may determine in the particular case whether the patient will or will not die.

Many years ago, before the days of aseptic surgery, a surgeon well known for his painstaking work and good results, said to me, when I was his surgical house pupil at the Massachusetts General Hospital, that the life of a surgeon was one of great anxiety and occasionally of much chagrin and unhappiness. He was at this time depressed by the death of a patient, a young woman with everything to live for—husband, children, riches—on whom he had operated for the repair of a lacerated perineum. If such things happened frequently, he said, the life of a surgeon would be unendurable. I have always remembered this remark, but I did not at that time realize its full significance. In estimating the weight of the responsibilities which rest on the surgeon, I have often recalled this case. "We must remember," Dr. Hodges used to say whenever there occurred an unexpected disaster which could be neither explained nor provided against, "that this is one of the contingencies of surgery." A death under the anesthetic, an uncontrollable hemorrhage, a pulmonary embolism, a fatal wound infection, not to mention such rare occurrences as homicidal and suicidal manias, and omitting entirely the disasters peculiar to each surgical procedure, these things will occur in spite of every precaution, and they are the contingencies of surgery—possibilities which attend even the most trivial surgical procedures.

With the advance of modern surgery, many of the horrors of the old days have been obviated, it is true, and the occurrence of others has been rendered infrequent; but there still remain, in all surgical cases, possibilities of disaster which the largest experience and the greatest care can not prevent; and we must not in any case, even the simplest, forget these possibilities. With the rare and unavoidable disasters, and with the common and avoidable ones—any of which, through errors in human judgment, may unexpectedly occur—the modern surgeon, who has under his care so many cases, is indeed fortunate if he has not at every moment some disturbing case and in every year some deplorable calamity. The surgeon reviewing his years of active practice can not but be impressed by the responsibilities of his profession. He recalls the frequent misgivings with which, on the strength of his fallible opinion, he has advised and performed operations; the excitement of a critical operation and the deep breath of thankfulness when he has succeeded in averting some grave complication; his forebodings—so frequently instinctive— of impending disaster, and the sinking of the heart as his forebodings become realities; the too often useless struggle against overwhelming odds; the distressful death; the severe self-criticism and biting regrets. And is not the surgeon, appreciating his own unfitness in spite of years of devotion, in the position to condemn those who lightly take up such burdens without preparation and too often without conscience?

The responsibilities of surgery are not, however, always appreciated even by those who are by education and experience qualified to bear them. I have heard such men say that the removal of an appendix in the so-called "interval" is a perfectly safe operation; that no surgeon ought ever to have a death after removal of the appendix in health or after any similar operation. It seems to me that one is indeed fortunate if he can look on the operation of appendectomy in the period of health with perfect equanimity, for it is in just such cases as these that I find the responsibility heaviest. When a patient has acute appendicitis with general peritonitis, the responsibility in operating is slight: the operation must be performed. There is no greater responsibility in this decision than there is in the decision of going to rescue a drowning child. When, however, the surgeon takes a patient who is in comparatively good health, makes him unconscious, opens his abdomen and removes his appendix, then the feeling of responsibility is to be compared only to that which one would feel if he were to throw a child into the sea and afterward jump overboard to save him!

From the moment the anesthesia is begun, to the time when the convalescence is complete, the surgeon will be held responsible for every complication and for every disaster—for acts of anesthetist, assistants and nurses.

In view of these facts, who should perform surgery? How shall the surgeon be best fitted for these grave duties? As a matter of right and wrong, who shall, in the opinion of the medical profession, advise and perform these responsible acts, and who shall not?

Surgical operations should be performed only by those who are educated for that special purpose. What, then, is the education that will fit a man to become a competent surgeon, and what are the qualities that go to make a good surgeon? Some men have good judgment in the advising of operations, with but little skill in performing them; others have bad judgment in the advising of operations, but splendid technic in performing them; still others are not only poor diagnosticians and men of bad judgment, but they are clumsy operators.

In considering these questions, I shall ask and try to answer another: What should be the education of the surgeon?

Important, if not essential qualifications for the surgeon, are strength, endurance and hopefulness. The surgeon should have the power of being cheerful under the most discouraging conditions; a persistence — it might almost be called an obstinacy—which will under no circumstances fail; a determination never to give up so long as the breath of life is in the patient. No matter what the diagnosis may be, no matter what the outlook may be, the only excuse for giving up the fight in surgery is either the death of the patient or the discharge of the surgeon. Human fallibility is great; and if the surgeon carries out this general rule of never giving up, he will see occasionally a surprising—even incredible—recovery.

Manual skill is of great help to the surgeon, especially in diseases which require the use of apparatus, as in orthopedics and fractures. The mechanical training of candidates is not sufficiently insisted on; yet the surgeon's reputation very largely depends on the actual performance of an operation. Mechanical skill in operating is not, however, to be compared with intellectual skill; but in the case of an intelligent young man the decision between surgery and some other profession might be dependent on mechanical ability.

The student should be thoroughly trained in mechanical work, he should learn the use of tools of all kinds—machinists', carpenters' and forging. On the rapid and skillful use of needle and thread many an operative reputation has been founded. Mechanical skill alone, however, is of little value in the equipment of the surgeon without those finer mental qualities which enable him to make, from intelligent observations, accurate decisions.

Some men are remarkably keen in this respect. A man may be able to see things and to describe them, but may not be able to tell the difference between two things which are very nearly alike. In the case of twins a man might not be able to describe the difference, no matter how careful an observer he might be (barring some such distinguishing mark as a scar), but he might be able always to tell them apart. So it is in distinguishing between certain crystals—for instance, between the crystals of beryl and the crystals of quartz—when perhaps the characteristic angles of crystallization are not to be seen. A crystal of beryl which could not by a written description be made distinguishable to the ordinary observer from a crystal of quartz could be instantly told by an experienced mineralogist. Betweeen two affections which are nearly alike the superficial observer would see little if any difference. It would be hard for a beginner or for a superficial observer to tell the difference between the tumor of an acute appendicitis and the tumor of a new growth at the ileocecal valve, if no history of the case were given; or to distinguish a uterine fibroid and a solid tumor of the ovary, a salpingitis and an appendicitis, a sarcoma of the breast and a cystic tumor of the breast, smallpox, chicken pox, smallpox and measles, and so on. Probably very few men could describe the difference between these affections, and yet an experienced observer would be able to tell at a glance which was which.

I have been interested in noting how the minds of students work, as shown at examinations and in the study of clinical cases. One is almost able to say: "This student will make a successful diagnostician, and his advice will always be good; that student will never amount to much as a diagnostician." In a recent examination at the Harvard Medical School the advanced students were asked to give the diagnosis, the prognosis, and the treatment in eight carefully described cases taken from my note-books. In some of these cases there had been a great difference of opinion among physicians of the largest experience; yet some of the students, interpreting the histories properly and drawing the correct conclusions, gave the right answer in every case. Many of these students did not show the learning of others who drew wrong conclusions in every case. The students whose deductions were in every case correct will without question make more successful practitioners than the students who, though exhibiting much more learning, picked out the unimportant features in the histories of the cases, and on these unimportant features based correct deductions, which were, as to the real lesion, always wrong. This examination in clinical surgery brought out in strong light the qualities necessary for the best equipment of the surgeon—namely, the power of grasping the essential features of a case and of basing on such evidence conclusions almost invariably correct.

Before studying medicine the student should be well grounded in botany, chemistry and physics. His education in the medical school, however, should be principally in what might be called the A B C's of medicine: anatomy, physiology and pathology. Most of his time should be devoted to the study of the human body in normal action (physiology), in abnormal action (living pathology); and to the study of the dead body (normal anatomy), and of the diseased dead body (pathologic anatomy). The most important thing is the study of pathology on the living. This branch of education, however, can not be extensively studied at the medical school or in the hospital. The surgeon begins it in the medical school, but he must continue it later at every possible opportunity. The allied sciences—chemistry, bacteriology and the specialties of medicine and surgery—should be a part of his education; but, as I have said, most of his time in practice should be devoted to the study of the healthy living body, the healthy dead body; the pathologic living and the pathologic dead.

In my recent teaching I have made use of the autopsy for the education of the students' touch, especially in abdominal diseases in which the surgeon is frequently obliged to depend on the evidences of his fingers to decide for continuance or abandonment of his operation. The history is read and the case is discussed. The abdominal incision is next made as if for operation. The student is then required to explore the abdominal cavity with his hand, and to record his opinion as to the lesion present and as to the condition of all the abdominal organs. If no disease is diagnosticated beforehand, he is required to give his opinion as to the condition of each organ. To some extent the diagnosis may be made on the pathologic appearances seen at autopsy; but the pathologic appearances during life are so different from those after death that the surgeon who depends exclusively on experience gained at the autopsy table is liable to err.

A thorough knowledge of practical anatomy, such as was insisted on in the preanesthetic days when the success of the operation was largely a matter of speed, should still be insisted on as the first and most important equipment of the operating surgeon. Not that the extraordinary skill and rapidity of some of the operators of those days is essential when anesthesia and asepsis make deliberate and careful dissections possible, yet there is, in my judgment, among even the experienced operators, a deplorable ignorance of normal anatomy. The freedom and rapidity with which cuts are made in close proximity to important structures is to the anatomist appalling. It explains, however, the frequency of the so-called "accidents" of surgery: urinary and fecal fistulæ, paralyses and hemorrhages. I would advise the surgeon, both in preparation and in active practice, to make use of every opportunity for dissection; to become so familiar with the human body that he can not fail to recognize every structure the moment the smallest portion of it is uncovered; to be able to proceed directly on his operative route without being obliged to halt for a moment to study his landmarks. Normal anatomy is quite as important in operative surgery as pathologic anatomy is in the understanding of disease. Anatomy should be, if not first, a strong second in the education of the surgeon.

The chief preparation of the surgeon, after the acquisition of the knowledge given him in his medical school courses, must be in direct contact with patients. The medical school will have qualified him to observe the normal working of the human body (physiology), the structure of the body (anatomy), the results of disease (pathology as illustrated on the dead). The courses will have given him an opportunity to see, in a very limited number of cases, the pathology of the living (symptoms as expressed at the bedside). He will have learned the theory of repair of wounds—inflammation, suppurations and all the processes which are erroneously spoken of as surgical pathology. In the ordinary courses of study during his four years at the medical school he will have a very limited experience. In order to become a surgeon qualified to bear the responsibilities of our profession, he will require an additional training, and that training must be thorough and prolonged. He must be brought into contact every day with surgical diseases in their clinical manifestations; and he must learn, by the observation of an enormous number of cases, to distinguish between diseases so closely resembling each other that he could only with the greatest difficulty describe the differences in words. It is first on this clinical experience that he must rely, and secondly on the observation during operations of the connection between symptoms previously noted and the lesion actually found. It follows that the best preparation that a man can have for becoming a practical surgeon is in the position of assistant. As a medical student his opportunity for observation is at the clinical work. At a distance, perhaps, or near at hand, as the case may be, he observes the examination of the case and the operation on the patient. In as many instances as possible he is required to take his own history and to make his own examination. If he gets an appointment as assistant in a hospital he has an opportunity of observing patients and studying them as carefully as his time permits, of assisting at operations and there seeing the lesions, of seeing in the autopsy room—in cases in which the result is fatal—the pathologic appearances. This is the best preparation that the medical schools and the hospitals offer. After this a course of study in Europe broadens the student's view and increases his experience.

Is this enough to round out a man's education so that he may assume the responsibility of surgery? This is so much better than the education of most men who practice surgery that one is inclined to answer in the affirmative; but I am considering the best education for the surgeon. I have no hesitation in saying that the proper fitting of a man for surgical practice requires a much longer experience as student and assistant than the most exacting schools demand. A man should serve four, five or six years as assistant to an active surgeon. During this period of preparation, as it were, as much time as possible should be given to observing the work of the masters of surgery throughout the world. Nothing broadens a man like observing the work of others. One should never give up visiting the clinics of the masters, no matter how experienced he may be. A man can not but become narrow in his views and limited in his resources, especially in emergencies, if his work has been confined to his own special clinic. Yet, on the other hand, is there not a danger that one may become a chronic student, an imitator of others, without originality or initiative? I believe that there is. I have seen a man hesitate between the teachings of Paris, Berlin, Vienna and London until he had to be prompted by his house surgeon into an American—at home—every-day successful procedure!

The importance of laboratory work—the so-called research work—in preparing a man to become a surgeon, is great. The necessity or the advisability of continuing in the work of active laboratory research admits of doubt. Certain qualities are essential to make a man a good worker in research. It requires quite different qualities to make a good surgeon. The fields are both infinitely broad; and I doubt whether a man can contribute much of value in the field of original research—in the sense of scientific research in the laboratory—and at the same time accomplish much in the field of practical surgery. The clinical man sees every day opportunities for research; problems arise which are of the greatest interest. It is for him to suggest lines for experimental work, but it is not for him to carry out the actual work itself.

In the larger sense, however, the surgeon is engaged in the work of original research. In the clinical manifestations of disease he alone sees the connection between cause and effect. Suggestions as to treatment, symptomatology, prognosis and operative methods occur to him in the course of his daily work; and practical advance in the treatment of disease comes mainly from the results of his observations at the bedside and at the operating table.

How may it best be brought about that surgery shall be in the hands of those only who are by education and experience best equipped to practice it?

Is it better to limit surgery to those who are given courses of instruction and degrees designed especially for the education of the surgeon, or would it be preferable so to educate public opinion that only those could be called on to practice surgery who were known to be well fitted for it?

The trouble with the latter question is that the public is easily deceived in medical matters. Nevertheless there is, I think, a strong public opinion in favor of the practitioners who are known to be surgeons of skill and experience. It is on this power of discrimination between the evil results and the good, and on the dependence of these results on skill, that we must chiefly rely in creating a sound public and professional opinion in favor of special experience and skill in the advising and in the performance of surgical operations, and in the practice of surgery in general.

A CASE OF SYSTEMIC BLASTOMYCOSIS, WITH BLASTOMYCETES IN THE SPUTUM.

DANIEL N. EISENDRATH, M.D.
AND
OLIVER S. ORMSBY, M.D.
CHICAGO.

Through the efforts of Drs. James Nevins Hyde and Frank Hugh Montgomery and other observers, cutaneous blastomycosis is now generally recognized as an entity. The number of reported cases of systemic blastomycosis being few, it seems justifiable to report more or less fully new cases as they occur, so that by a study of the entire group it will be possible definitely to place the disorder in its proper position in medicine. There are now on record four cases of systemic blastomycosis, in which the causative organism appears identical. These were recorded by Busse and Buschke,[1] Montgomery and Walker,[2] Ormsby and Miller[3] and Cleary.[4] Three of the cases were in Chicago, and two of these occurred in the practice of Drs. Hyde and Montgomery. Another case which closely conforms, and which by some observers is classed here, was that reported by Ophüls and Moffitt[5] of California. In these various cases, similar symptoms were presented before death and similar findings were made postmortem, yet marked differences also occurred. In the various cases, the larynx, trachea, lungs, pleura, myocardium, liver, spleen, pancreas, kidneys, adrenals, mesentery, lymph glands, bones, joints, subcutaneous and cutaneous tissues were the seat of the lesions, the organism being found in all these localities. The microscopic findings in all of these cases were similar, differing chiefly in extent of distribution or destruction. The process often resembled pyemia, multiple abscesses occurring in various organs and tissues of the body. In one case (that of Ormsby and Miller), the usual picture presented in the skin by the chronic, purely cutaneous cases was almost entirely absent, only one lesion possessing this resemblance. In another (that of Cleary), no cutaneous lesions were present. These cases resemble tuberculosis, both clinically and pathologically. This is evident from the findings in the past. The miliary tubercles found in the lungs, liver and elsewhere have a close resemblance to the miliary tubercles of tuberculosis in the same situations; and the chief responsibility of those recording cases in the future will be to eliminate the presence of tuberculosis.

We are indebted to Dr. M. L. Blatt for aid in procuring material for histologic study, and to Dr. H. L. Wolf, house surgeon at Cook County Hospital, for assistance in the work in this case.

Patient.—Polish laborer, aged 33, married and has two healthy children.

History.—His illness began in February, 1904. He was admitted to Cook County Hospital in February, 1905, and assigned to the service of Dr. Eisendrath. He speaks no English, so a satisfactory history through an interpreter was hard to obtain. It is probable that he has had the usual diseases of childhood. He denies venereal infection; he has been a moderate smoker of cigarettes, and drinks occasionally. His surroundings at home were most insanitary.

Present Illness.—The present disease began in February, 1904. He has given two versions of the beginning. The following was the last and seems most reliable: He states that the first noticeable departure from his usual good health consisted in a feeling of discomfort involving the chest on the right side, extending through from front to back. This lasted for a time, and, in fact, is still present, being better and worse at intervals. In June, four months from the beginning, his first cutaneous lesion appeared. This was located below the left ankle and extended down to the heel, and eventually became a little larger than a dollar. Shortly afterward the other lesions appeared, but it is impossible to tell their exact mode of development. In addition to this area on the left leg, the right leg had several large lesions, also the right and left forearm, and the face, chin and neck, especially on the right side (Fig. 1). About November, 1904, he suffered great muscular weakness, and marked swelling of the feet and ankles occurred. This gradually increased until he was wholly unable to work. He stopped work in December. He stated that with the onset of the original pain he employed a physician for two months and was benefited by the treatment. Something was applied to the skin by the physician which made the skin sore, but this soon healed, and was entirely different from the cutaneous lesions present on his admission to the hospital.

Examination.—On his admission to the hospital in February, 1905, he presented lesions on all the above-mentioned areas, and was very much emaciated, pale, anemic, exceedingly weak and had some elevation of temperature. Marked edema was present in the ankles, feet, face and arms. His nails were clubbed, and moderate inguinal adenopathy was noted.

Cutaneous Lesions: There was present on the left leg, below the ankle, a lesion about the size of a silver dollar. One on the right leg (Fig. 2.), on the lower third, occupying the outer and posterior surface, measured about four by two and half inches. This was oval in shape, and was joined below by a similar lesion, of about the same size, situated over the external malleolus. Two or three similar but smaller lesions were in the neighborhood. All these lesions were quite superficial, the larger part of each being an ulcer, crust covered in places, open in others. There was little induration, but considerable sanguinopurulent discharge. The edge of the ulcer was slightly elevated and presented a bluish-red halo, in which there were located a few miliary abscesses. In some parts of the area a papillomatous condition was present. The lesion on the arm was a subcutaneous nodule, which later softened and was incised, and from the sinus left after this procedure, and from both the lesions on the legs, the organism of blastomycosis was demonstrated by us in pus before the Chicago Medical Society,[6] March 8, 1905. There was also present a large swelling on the left forearm, which apparently involved the whole circumference. It began about two and one-half inches below the elbow joint and extended down the forearm about four inches. It involved both sides of the forearm, and suggested the possibility of bone involvement. In a skiagraph of this lesion the bone appeared normal. This swelling was later incised and the same characteristic discharge released. Material from this swelling was inoculated into two guinea-pigs on April 26. There is still involvement in this area. The lesions on the face (Fig. 1), on account of the different anatomic site, presented a slightly different picture. Here they protruded more extensively above the level of the skin and were papillomatous; some were even verrucous. There was much discharge and marked crusting. The part chiefly involved was the right side of the face, the right side of the neck and the lower lip, extending to the vermillion border.

Bacteriologic Examination.—On March 22 pus was removed from a subcutaneous unruptured abscess situated on the left forearm and inoculated on various media and later in animals. Pure cultures of blastomycetes grew on all the tubes. This pus was stained for tubercle bacilli with negative results. Blood cultures have been negative, as has also examination of the urine relative to blastomycetes. Albumin and casts were present in the urine, however. On March 22 tuberculin was given with negative results. No tubercle bacilli have been demonstrated in sections or pus.

Course of the Disease.—Although the patient constantly denied having a cough or expectoration of any moment, and although his attendants at the hospital had not noticed these symptoms, on April 26 we were able to collect a large amount of blood-stained, mucopurulent sputum, in which the organism was plentifully found, as is well shown in Figure 3. On May 1 the following physical findings were recorded by the house physician, Dr. Morrell:

> "Liver and spleen not palpable. Abdomen tympanitic: Lungs: Right apex and upper lobe on right side dull posteriorly. Bronchophony and bronchial breathing present. Lung expansion practically absent. A few râles present in the right lower lobe near the axillary line. The left lung hyper-resonant except at apex."

During his four months' sojourn at the hospital, his temperature ranged from 98.6 to 102.8; his pulse from 88 to 116; his respiration from 20 to 28. The latter half of the time the temperature was considerably lower. As a rule, there was an exacerbation each evening. Under large doses of potassium iodid internally, with radiotherapy, antiseptic dressings and surgical interference locally, marked improvement occurred.

On July 7, when the patient left the hospital, he was much improved in every way. The cutaneous lesions were nearly all healed, he had gained in weight, and had but little fever. On leaving the hospital he passed from our observation for a few weeks. He had stopped the treatment, and when seen by us at his home, five weeks later, he had suffered a relapse. He was suffering with marked pain in the right chest, several cutaneous lesions were active again, and the sinuses leading from the deep lesions on the forearm had reopened.[7]

HISTOPATHOLOGY OF A CUTANEOUS LESION.

As this case presented the histologic picture common to this disease, a detailed description is not given here. Outside of the chief area of involvement there is vascular dilatation and perivascular cellular infiltration, scattered irregularly through the entire depth of the corium. Over this region the epidermis is unaltered, except for slight hyperpigmentation here and there. There is also slight edema of the collagen. Approaching the diseased area, the cellular infiltration increases until in the center there is a large, fairly well-defined area of intense infiltration. The epidermis over this region shows marked hypertrophy, which is very characteristic of this disorder. With low power (Fig. 4) one is struck with the marked resemblance this picture presents to lupus vulgaris—the marked epidermal hypertrophy; the intense cellular infiltration, containing groups of giant-cells; the comparative absence of collagen and elastin, etc. Scattered all throughout, however, is the double-contoured organism of blastomycosis, occurring chiefly in budding forms, and practically every giant cell contains two or more of these organisms (Fig. 5). In addition to giant cells, there are some polynuclear cells, very many polymorphonuclear leucocytes, some mononuclear leucocytes, some plasma cells, and many connective tissue cells. No tubercle bacilli have been found.

CULTURES AND ANIMAL EXPERIMENTS.

The first cultures taken at Cook County Hospital on March 8 were made from open ulcers and a sinus on the forearm, and although the organism was fairly abundant in smears made from this pus, it failed to grow on the media. On March 22 pus was removed from a subcutaneous abscess on the left forearm, which was inoculated on various media. On March 28, six days after this inoculation, growth was plainly visible, and after this time the cultures grew rapidly. These proved to be pure cultures of blastomycetes. The organism both in the tissues and pus and on media differed in no essential particular from those described by Montgomery[8] in his report of three years ago, so only a brief description is given here. In the pus they occurred as circular and budding forms, having a double contour and the usual refractile capsule. On media the growth varied. It presented a moist, pasty surface on glycerin-agar (Fig. 6), with at times a wormy appearance, or else presenting large folds and depressions. Microscopically, these cultures showed many oval and circular organisms, some budding ones and much mycelial formation, the latter being both coarse and fine and containing sporules (Figs. 7 and 8). Lateral conidia occurred. On glucose-agar (Fig. 9*) the growth was more dry, white, and presented aereal hyphæ; and microscopically, there were fewer circular and budding organisms and more fine mycelia. On both glucose and glycerin agar the media were penetrated to a considerable depth in a semicircular manner.

On blood serum the growth was also moist and pasty,

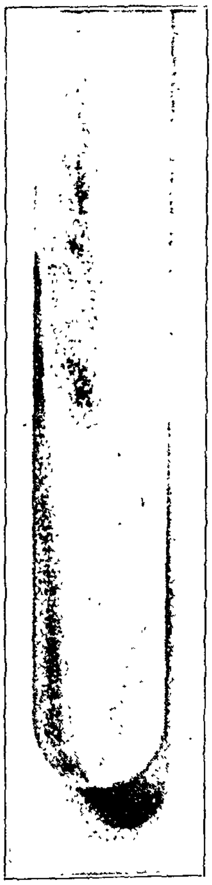

Fig. 9.—Microphotograph. Same as Fig. 6, except growth here is on glucose-agar.

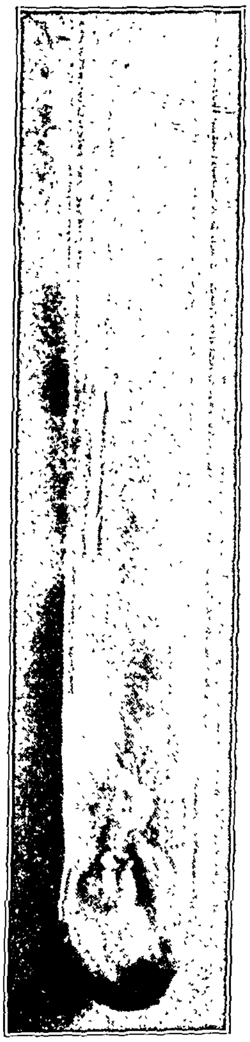

Fig. 10.—Subculture of organism on glycerin-agar, originally from sputum.

and presented a greater proportion of the circular and oval organisms. The cultures taken from the cutaneous lesions, the subcutaneous abscesses and the sputum (Fig. 10) all appeared similar. Subcultures had to be made to obtain pure cultures from the sputum. On April 26, two guinea-pigs were inoculated subcutaneously with an emulsion of pus and granulation tissue, removed from the forearm by incision into an unruptured, deep-seated abscess. Both these animals developed a local lesion of blastomycetic infection at the point of inoculation and surrounding it for half an inch in each direction. These lesions remained for a few weeks, then healed, leaving only a slight atrophic area. On August 12, one of these animals was chloroformed and a thorough postmortem examination made. The subcutaneous fat was intact, the glandular system negative and all the internal organs healthy. There was some local change where the inoculation was made, but no disease or organisms were present. As the other animal inoculated at the same time was healthy and fat, and as more than three months had elapsed since the inoculation, this work in these two animals was negative as to tuberculosis. On May 14, three guinea-pigs were inoculated, one with 15 mm. of the hemorrhagic mucopurulent sputum. This animal was accidentally killed three weeks later by a rat. The postmortem was made by Dr. Adolph Gehrman, who reported negative findings. Had tubercle bacilli been present in the sputum, some evidence of their development would have been evident in the three weeks. A second animal was inoculated subcutaneously with pus previously removed from a subcutaneous abscess in the left forearm. This animal, after three months, is perfectly healthy and is being kept. The third animal received 15 mm. of an emulsion of sterile water and a pure culture of the blastomycetes obtained March 22 from an unruptured abscess on the forearm. This animal was posted August 14, and apparently had overcome the attack, as it was perfectly healthy and no organisms were found in any of the tissues or organs. With negative results from four susceptible animals, such as guinea-pigs inoculated with such likely material as mucopurulent sputum, pus and granulation tissue from an abscess wall, it is probable that no tubercle bacilli were present in this case. The negative findings with the inoculation of the pure culture of the blastomycetic organism is not especially significant, as the guinea-pig is not very susceptible to general infection with this organism, though general infection has occurred several times.

A BRIEF REVIEW OF OTHER RECORDED CASES.

In the first case, that of Busse and Buschke,[1] cutaneous, subcutaneous, visceral and bone lesions were present. Early there formed an abscess on the tibia, from which situation the disease spread to the knee joint. There is uncertainty as to which appeared first, the tibial abscess or the cutaneous lesions. The patient succumbed in from thirteen to eighteen months from the beginning of the disease, having as general symptoms marasmus, irregular pulse and temperature. The organism, which was found abundantly in the pus and tissues, was round or oval and developed by budding. In the second case, that of Walker and Montgomery,[2] cutaneous blastomycosis of several years' duration was followed by systemic involvement. This patient was operated on, curettage and cauterization being employed. Nine days after the operation there occurred elevation of temperature, increased pulse rate and rapid respiration; the appetite failed, emaciation occurred, with dyspnea, the patient dying in forty-three days.

It is interesting to note that this case was under Dr. Montgomery's observation several years before cutaneous blastomycosis was recognized, and was classed by him as an unusual tuberculosis. At the postmortem, Dr. Walker considered the patient had died of acute miliary tuberculosis. Later, both gentlemen, having their attention called to the subject of blastomycosis, recalled this case and investigated their old slides, and independently recognized it as an example of cutaneous and visceral blastomycosis. The organism as seen in the sections was circular or oval and developed by budding. In the third case, that of Ormsby and Miller,[3] the patient's history was suggestive of tuberculosis. It was briefly thus: The patient caught cold, which settled in his chest. He coughed and had some blood-streaked expectoration and became very weak. Two months later the first cutaneous lesion appeared. For a time, improvement in his general condition occurred, then he became pale, emaciated, anemic, had loss of appetite, coated tongue and a foul breath. The urine was negative. The temperature was elevated, pulse rapid and respiration increased. Large numbers of subcutaneous nodules and abscesses and cutaneous ulcers occurred. Physical examination of the lung showed bronchial breathing and other evidences of involvement. Laryngitis was present. This latter proved to be due to ulceration induced by the organism of blastomycosis. Repeated examinations of the sputum were negative as to tubercle bacilli. Tuberculin reaction repeated was negative. In this case, special effort was devoted to excluding tuberculosis. Thorough examination of smears made from pus from the various organs and tissues of the body all failed to reveal tubercle bacilli. Animal inoculation and culture experiments were all negative as to tuberculosis. In all situations large numbers of blastomycetes were always demonstrated. Cultures were readily obtained and animal experiments were successful with the blastomycetes. Drs. Otis and Evans[9] did thorough pathologic and bacteriologic work on this case, and later reported in detail the biology of the organism. From their findings they ruled out tuberculosis. It is a point of scientific interest to note that one of the operators at the autopsy in this case was inoculated with and shortly afterward developed blastomycosis. This organism was found always in the budding form in the tissue and pus, but on media mycelia formed. In the fourth case, that of Cleary,[4] it is interesting to note that special symptoms masked the general infection, so that the diagnosis of blastomycosis was made postmortem. The patient's general symptoms were a cold, cough, mucopurulent expectoration, loss of weight, anorexia, hoarseness and edema of the feet and legs. The urine contained albumin and granular and hyalin casts. The temperature was always subnormal and there were no cutaneous lesions. No tubercle bacilli were found in the sputum. At the autopsy, the usual budding organism was found in the lungs, kidneys, liver, spleen, adrenals and myocardium.

This group of cases resembles closely those cases reported in California and elsewhere under the title of protozoic dermatitis, both clinically and pathologically, one of the main differences being the fact that in the protozoic cases the organism does not reproduce by budding in pus and tissues, but develops by endogenous spore formation. In the case of Ophüls and Moffitt[5] which is

classed by some as blastomycosis and by others as protozoic disease, the organism closely resembles in culture the blastomycetes, but in the tissue these develop only by spore formation and not by budding. The clinical and pathologic findings in this case are very similar to the blastomycosis cases.

INFECTION ATRIUM.

In two of the foregoing cases, the lungs seemed to have been the first point infected. In one other the skin was first attacked, general infection following. In the other the question is open as to which was first, the skin lesion or the tibial abscess. In our present case the lungs were apparently attacked first.

REVIEW OF PRESENT CASE.

First. This patient is suffering with a constitutional disease, as evidenced by the clinical symptoms, which show involvement of the lungs, kidneys, skin and subcutaneous tissues.

Second. It seems probable that the lungs were the first point of attack, and they are still markedly involved.

Third. Although tuberculosis in this case is simulated, no tubercle bacilli could be demonstrated, microscopically, culturally or experimentally, and tuberculin reaction proved negative.

Fourth. The organism of blastomycosis has been demonstrated abundantly in cutaneous lesions, subcutaneous unruptured abscesses (in pure culture), and in the sputum.

Fifth. Although the disease responded to, and greatly improved under, potassium iodid, the patient is far from well and future developments will be noted.

Sixth. With the organism from this patient, we have produced only local lesions of blastomycosis, our efforts being directed chiefly to the elimination of a possible tubercle bacillus infection.

PENETRATING WOUNDS OF THE ABDOMEN.*

RANDOLPH WINSLOW, M.D.
BALTIMORE.

Penetrating wounds of the abdomen occur with considerable frequency in civil as well as in military practice, and until recently have been the most uniformly fatal of all injuries. As much of our knowledge of this class of injuries has been derived from the experience of the civil war, in preantiseptic times, so we may expect to revise or to confirm our views on this subject by the experience of the surgeons now engaged with the armies in the far East, when they shall have the opportunity to collate their experiences. My experience in these cases is confined entirely to those injuries occurring in civil life, in which the wounds have been inflicted by pistol or rifle balls or with knives and scissors. The larger number of these injuries are inflicted by bullets, while a large minority are due to stabs. As a rule, the traumatisms resulting from gunshot wounds are much greater than those dependent on cutting, and the mortality is higher. This is due to the fact that an incised wound heals more readily than a contused wound, and that the injuries are more localized when caused by a stab than when caused by bullets.

SYMPTOMS.

The symptoms of a penetrating wound are by no means always well defined, and there may be serious and even fatal lesions of the solid or hollow viscera, with very slight external manifestations. The most obvious symptom is the location of the wound of entrance; when this is on the anterior abdominal wall, it is fair to presume that the peritoneal cavity has been entered, and the track of the missile or stab should be explored in such cases. The exploration should not be the old haphazard method of probing with an unclean finger or probe, but the abdomen should be thoroughly cleansed and the track incised carefully, and if it is found to lead into the peritoneal cavity laparotomy should be done at once and injuries of the viscera and vessels sought for. This procedure should not be undertaken until the patient has been conveyed to the place at which he is to remain, which should be a well-equipped hospital when possible; neither should it be performed by an inexperienced and ill-equipped surgeon if it is possible to obtain the services of one who has the requisite qualifications. Sometimes the omentum will protrude from the wound, but it is very seldom that fecal contents or gas will escape externally. There may be a wound of exit as well as of entrance, but the bullets are retained usually in civil practice, and even when there are multiple wounds they may not indicate that the missiles have passed through the body, but that the patient has been shot in opposite directions. No special significance can be placed on the symptom of shock; in many cases it is entirely absent, but when present generally indicates hemorrhage. It is somewhat difficult to determine whether gunshot or stab wounds of the posterior abdominal or lower thoracic walls have entered the peritoneal cavity, and they also should be explored by incising the track of the ball or knife or in doubtful cases by making an exploratory laparotomy.

Wounds of the thorax as high as the fifth and sixth ribs frequently penetrate the peritoneal cavity and inflict serious injuries to the abdominal viscera. Such wounds must always be regarded as possible penetrating traumatisms of the belly. It is quite true in military practice that a person shot in the head, neck, thorax or extremities may have penetration of the peritoneum, but in civil life this is not generally the case. Vomiting of blood is a sign of injury to the stomach or upper intestine, and when associated with a wound suitably located makes the diagnosis reasonably sure. The bladder should be catheterized, and if it contains bloody urine a lesion of this viscus or of the kidneys or ureters is suggested. The escape of blood from the anus is not frequent, but when it does occur would indicate injury to the lower part of the intestinal tract.

The diagnosis of extent of injury done can only be determined by an operation or by postmortem examination.

PROGNOSIS.

The prognosis of penetrating wounds of the abdomen is exceedingly grave, and depends on the organs and structures injured, on the nature of the traumatism, on the degree of emptiness or fullness of the hollow viscera when injured, and on the presence or absence of serious hemorrhage. Wounds of the upper part of the abdomen are not so fatal as are those below the umbilicus, and small perforations of the stomach may not leak. Injuries of the liver, spleen and kidneys, if not extensive, are frequently recovered from. Gunshot wounds of the intestines in civil practice are usually fatal when unoperated on. In the civil war the mortality of gunshot wounds of both intestines was 80.3 per cent., while the same injuries to the small intestines

were followed by practically 100 per cent. of fatality. A bullet traversing the abdomen from before backward usually produces fewer lesions than one crossing the same cavity transversely or obliquely.

---

* Read in the Section on Surgery and Anatomy of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

Stab wounds are probably followed by more hemorrhage than gunshot wounds, but the visceral lesions are not usually so extensive and can be repaired more readily and with less handling of the intestines, hence with less danger to the patient. Gunshot wounds of the pelvis are likely to pass into the pelvic cavity and to injure the organs and vessels situated therein either intraperitoneally or extraperitoneally, and with a high mortality.

TREATMENT.

The treatment of penetrating wounds of the abdomen is not yet definitely settled. Under an expectant treatment the mortality is enormous, and it was due to this fact that the elder Gross, in 1843, after a series of elaborate experiments on animals, advocated suturing the intestinal wounds; but his views were far in advance of his day, and his suggestions went unheeded. The frightful mortality of the civil war did not serve to impress the lesson any better, and it was not until 1881 that J. Marion Sims, as a last legacy to the medical profession, which he had already enriched in so many ways, insisted that these injuries should be treated by operation. The lesson was now learned, and soon successful operations were being performed for the relief of perforating wounds of the hollow viscera. It was supposed that the question of the proper treatment of penetrating wounds had been permanently settled in favor of laparotomy and suture of the lesions, but the faith of the profession has been somewhat shaken by the experience of the surgeons during the Spanish-American and Boer wars. According to the surgeon-general's report for 1899, there occurred 44 penetrating wounds of the abdomen in the U. S. Army, of which 30 died, a mortality of 68.2 per cent. In those cases where laparotomy was performed, the mortality was nearly 100 per cent.; hence a doubt is cast on the advisability of operating on such cases in military practice. In the South African war, the British surgeons also had to modify their views in regard to the propriety of operation, as many patients recovered without laparotomy and but few when it was performed. The essential difference between the mortality of these injuries at the present time in military practice from that of earlier wars is due to the small caliber projectile, steel or nickel jacketed, and the great velocity of the missiles propelled by modern firearms. The long, narrow bullet, projected with great speed, penetrates the tissues cleanly, does not become deflected, and is usually aseptic; hence, many serious wounds heal in a typical manner. In South Africa the wounded usually reached the operating hospital only after quite a long delay, and, as the climate is dry, water scarce, dust storms frequent and flies abundant, infection occurred very readily and operations were unsuccessful; hence, it was the part of wisdom to trust these cases to Nature rather than to perform laparotomy.

These conditions do not obtain in civil practice; the bullets are usually round or conical in shape, moving with a low velocity and extensively lacerating the intestines and other organs; the balls are not aseptic, and infection is of frequent occurrence, and death follows in a vast majority of cases when laparotomy is not done. I wish, therefore, to insist that penetrating stab and gunshot wounds of the abdomen occurring in civil life should be subjected to operation. In this class of cases, at least, the principle of operative interference has been fully established, and one is no longer obliged to apologize for the performance of laparotomy, but is under the necessity of defending himself if he fails to give his patient the benefit of an operation. The operation should be done at the earliest practicable moment before there is extensive fecal extravasation, which will certainly occur if the intestines are perforated, and peristalsis is set up. Do not wait for symptoms of intestinal *injury, but operate at once.* Every hour's delay adds very materially to the mortality; after the lapse of 24 hours nearly every case of intestinal perforation terminates fatally from suppurative peritonitis. As shock is usually due to bleeding, it is no contraindication for operation, and laparotomy should be done at once, and the bleeding vessels secured by clamp or ligature or controlled by pressure. Stimulation, however, by strychnia, digitalis or salt solution should also be employed. While the median incision is usually the best, as it affords greater access for the systematic exploration of the abdominal viscera, it may be preferable in some cases to make the laparotomy at the site of the external wound if only a small portion of the cavity has been traversed. The first duty of the operator will be to search for and to control bleeding vessels if active hemorrhage has taken place. After the arrest of bleeding, a careful search should be made for lesions of the hollow viscera, stomach, intestines, gall bladder and urinary bladder. I wish especially to emphasize the importance of a careful search of all parts of the intestinal tube, as the instances are not a few in which perforations have been overlooked.

WOUNDS OF THE STOMACH.

The stomach, being a large and fixed organ in the upper part of the abdominal cavity, is especially likely to be penetrated by wounds of the lower thoracic and upper abdominal regions. The penetration may involve the anterior wall alone or both surfaces may be perforated. It is necessary, therefore, to explore both surfaces of this viscus unless it is certain that only one penetration has occurred. At times the bullet is lodged in the stomach, in which case there will only be one hole in the viscus. The exploration of the posterior surface of the stomach is accomplished by tearing through the great omentum, when by sight and touch perforations may be discovered. Ordinarily it will not be difficult to suture the lesions on the anterior wall of the stomach, but when these are situated high up toward the cardiac orifice or at the extreme fundus it may be necessary to make an aditional incision in order to do so, or to divide one or more ribs. It may be impossible to reach some perforations on the posterior wall. Often the stomach is full when wounded, and there is a free escape of its contents into the greater or lesser peritoneal cavities, rendering a careful cleansing of these parts essential. The contamination of the lesser peritoneal cavity is especially serious, as it is difficult to cleanse it properly, and efficient gauze drainage ought to be employed. It may be best to drain through the back, as well as anteriorly.

Gunshot wounds of the stomach are frequently complicated with injuries of the lungs, diaphragm, liver, gall bladder, spleen, kidneys, pancreas, intestines and large vessels; hence, a high mortality follows, with or without operation. In the civil war four incised and punctured wounds of the stomach were observed, all of which terminated fatally. "One incontestable recovery from a shot perforation, a few recoveries from shot

classed by some as blastomycosis and by others as protozoic disease, the organism closely resembles in culture the blastomycetes, but in the tissue these develop only by spore formation and not by budding. The clinical and pathologic findings in this case are very similar to the blastomycosis cases.

INFECTION ATRIUM.

In two of the foregoing cases, the lungs seemed to have been the first point infected. In one other the skin was first attacked, general infection following. In the other the question is open as to which was first, the skin lesion or the tibial abscess. In our present case the lungs were apparently attacked first.

REVIEW OF PRESENT CASE.

First. This patient is suffering with a constitutional disease, as evidenced by the clinical symptoms, which show involvement of the lungs, kidneys, skin and subcutaneous tissues.

Second. It seems probable that the lungs were the first point of attack, and they are still markedly involved.

Third. Although tuberculosis in this case is simulated, no tubercle bacilli could be demonstrated, microscopically, culturally or experimentally, and tuberculin reaction proved negative.

Fourth. The organism of blastomycosis has been demonstrated abundantly in cutaneous lesions, subcutaneous unruptured abscesses (in pure culture), and in the sputum.

Fifth. Although the disease responded to, and greatly improved under, potassium iodid, the patient is far from well and future developments will be noted.

Sixth. With the organism from this patient, we have produced only local lesions of blastomycosis, our efforts being directed chiefly to the elimination of a possible tubercle bacillus infection.

PENETRATING WOUNDS OF THE ABDOMEN.*

RANDOLPH WINSLOW, M.D.
BALTIMORE.

Penetrating wounds of the abdomen occur with considerable frequency in civil as well as in military practice, and until recently have been the most uniformly fatal of all injuries. As much of our knowledge of this class of injuries has been derived from the experience of the civil war, in preantiseptic times, so we may expect to revise or to confirm our views on this subject by the experience of the surgeons now engaged with the armies in the far East, when they shall have the opportunity to collate their experiences. My experience in these cases is confined entirely to those injuries occurring in civil life, in which the wounds have been inflicted by pistol or rifle balls or with knives and scissors. The larger number of these injuries are inflicted by bullets, while a large minority are due to stabs. As a rule, the traumatisms resulting from gunshot wounds are much greater than those dependent on cutting, and the mortality is higher. This is due to the fact that an incised wound heals more readily than a contused wound, and that the injuries are more localized when caused by a stab than when caused by bullets.

SYMPTOMS.

The symptoms of a penetrating wound are by no means always well defined, and there may be serious and even fatal lesions of the solid or hollow viscera, with very slight external manifestations. The most obvious symptom is the location of the wound of entrance; when this is on the anterior abdominal wall, it is fair to presume that the peritoneal cavity has been entered, and the track of the missile or stab should be explored in such cases. The exploration should not be the old haphazard method of probing with an unclean finger or probe, but the abdomen should be thoroughly cleansed and the track incised carefully, and if it is found to lead into the peritoneal cavity laparotomy should be done at once and injuries of the viscera and vessels sought for. This procedure should not be undertaken until the patient has been conveyed to the place at which he is to remain, which should be a well-equipped hospital when possible; neither should it be performed by an inexperienced and ill-equipped surgeon if it is possible to obtain the services of one who has the requisite qualifications. Sometimes the omentum will protrude from the wound, but it is very seldom that fecal contents or gas will escape externally. There may be a wound of exit as well as of entrance, but the bullets are retained usually in civil practice, and even when there are multiple wounds they may not indicate that the missiles have passed through the body, but that the patient has been shot in opposite directions. No special significance can be placed on the symptom of shock; in many cases it is entirely absent, but when present generally indicates hemorrhage. It is somewhat difficult to determine whether gunshot or stab wounds of the posterior abdominal or lower thoracic walls have entered the peritoneal cavity, and they also should be explored by incising the track of the ball or knife or in doubtful cases by making an exploratory laparotomy.

Wounds of the thorax as high as the fifth and sixth ribs frequently penetrate the peritoneal cavity and inflict serious injuries to the abdominal viscera. Such wounds must always be regarded as possible penetrating traumatisms of the belly. It is quite true in military practice that a person shot in the head, neck, thorax or extremities may have penetration of the peritoneum, but in civil life this is not generally the case. Vomiting of blood is a sign of injury to the stomach or upper intestine, and when associated with a wound suitably located makes the diagnosis reasonably sure. The bladder should be catheterized, and if it contains bloody urine a lesion of this viscus or of the kidneys or ureters is suggested. The escape of blood from the anus is not frequent, but when it does occur would indicate injury to the lower part of the intestinal tract.

The diagnosis of extent of injury done can only be determined by an operation or by postmortem examination.

PROGNOSIS.

The prognosis of penetrating wounds of the abdomen is exceedingly grave, and depends on the organs and structures injured, on the nature of the traumatism, on the degree of emptiness or fullness of the hollow viscera when injured, and on the presence or absence of serious hemorrhage. Wounds of the upper part of the abdomen are not so fatal as are those below the umbilicus, and small perforations of the stomach may not leak. Injuries of the liver, spleen and kidneys, if not extensive, are frequently recovered from. Gunshot wounds of the intestines in civil practice are usually fatal when unoperated on. In the civil war the mortality of gunshot wounds of both intestines was 80.3 per cent., while the same injuries to the small intestines

were followed by practically 100 per cent. of fatality. A bullet traversing the abdomen from before backward usually produces fewer lesions than one crossing the same cavity transversely or obliquely.

---

* Read in the Section on Surgery and Anatomy of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

Stab wounds are probably followed by more hemorrhage than gunshot wounds, but the visceral lesions are not usually so extensive and can be repaired more readily and with less handling of the intestines, hence with less danger to the patient. Gunshot wounds of the pelvis are likely to pass into the pelvic cavity and to injure the organs and vessels situated therein either intraperitoneally or extraperitoneally, and with a high mortality.

TREATMENT.

The treatment of penetrating wounds of the abdomen is not yet definitely settled. Under an expectant treatment the mortality is enormous, and it was due to this fact that the elder Gross, in 1843, after a series of elaborate experiments on animals, advocated suturing the intestinal wounds; but his views were far in advance of his day, and his suggestions went unheeded. The frightful mortality of the civil war did not serve to impress the lesson any better, and it was not until 1881 that J. Marion Sims, as a last legacy to the medical profession, which he had already enriched in so many ways, insisted that these injuries should be treated by operation. The lesson was now learned, and soon successful operations were being performed for the relief of perforating wounds of the hollow viscera. It was supposed that the question of the proper treatment of penetrating wounds had been permanently settled in favor of laparotomy and suture of the lesions, but the faith of the profession has been somewhat shaken by the experience of the surgeons during the Spanish-American and Boer wars. According to the surgeon-general's report for 1899, there occurred 44 penetrating wounds of the abdomen in the U. S. Army, of which 30 died, a mortality of 68.2 per cent. In those cases where laparotomy was performed, the mortality was nearly 100 per cent.; hence a doubt is cast on the advisability of operating on such cases in military practice. In the South African war, the British surgeons also had to modify their views in regard to the propriety of operation, as many patients recovered without laparotomy and but few when it was performed. The essential difference between the mortality of these injuries at the present time in military practice from that of earlier wars is due to the small caliber projectile, steel or nickel jacketed, and the great velocity of the missiles propelled by modern firearms. The long, narrow bullet, projected with great speed, penetrates the tissues cleanly, does not become deflected, and is usually aseptic; hence, many serious wounds heal in a typical manner. In South Africa the wounded usually reached the operating hospital only after quite a long delay, and, as the climate is dry, water scarce, dust storms frequent and flies abundant, infection occurred very readily and operations were unsuccessful; hence, it was the part of wisdom to trust these cases to Nature rather than to perform laparotomy.

I wish, therefore, to insist that penetrating stab and gunshot wounds of the abdomen occurring in civil life should be subjected to operation. In this class of cases, at least, the principle of operative interference has been fully established, and one is no longer obliged to apologize for the performance of laparotomy, but is under the necessity of defending himself if he fails to give his patient the benefit of an operation. The operation should be done at the earliest practicable moment before there is extensive fecal extravasation, which will certainly occur if the intestines are perforated, and peristalsis is set up. Do not wait for symptoms of intestinal injury, but operate at once. Every hour's delay adds very materially to the mortality; after the lapse of 24 hours nearly every case of intestinal perforation terminates fatally from suppurative peritonitis. As shock is usually due to bleeding, it is no contraindication for operation, and laparotomy should be done at once, and the bleeding vessels secured by clamp or ligature or controlled by pressure. Stimulation, however, by strychnia, digitalis or salt solution should also be employed. While the median incision is usually the best, as it affords greater access for the systematic exploration of the abdominal viscera, it may be preferable in some cases to make the laparotomy at the site of the external wound if only a small portion of the cavity has been traversed. The first duty of the operator will be to search for and to control bleeding vessels if active hemorrhage has taken place. After the arrest of bleeding, a careful search should be made for lesions of the hollow viscera, stomach, intestines, gall bladder and urinary bladder. I wish especially to emphasize the importance of a careful search of all parts of the intestinal tube, as the instances are not a few in which perforations have been overlooked.

WOUNDS OF THE STOMACH.

The stomach, being a large and fixed organ in the upper part of the abdominal cavity, is especially likely to be penetrated by wounds of the lower thoracic and upper abdominal regions. The penetration may involve the anterior wall alone or both surfaces may be perforated. It is necessary, therefore, to explore both surfaces of this viscus unless it is certain that only one penetration has occurred. At times the bullet is lodged in the stomach, in which case there will only be one hole in the viscus. The exploration of the posterior surface of the stomach is accomplished by tearing through the great omentum, when by sight and touch perforations may be discovered. Ordinarily it will not be difficult to suture the lesions on the anterior wall of the stomach, but when these are situated high up toward the cardiac orifice or at the extreme fundus it may be necessary to make an aditional incision in order to do so, or to divide one or more ribs. It may be impossible to reach some perforations on the posterior wall. Often the stomach is full when wounded, and there is a free escape of its contents into the greater or lesser peritoneal cavities, rendering a careful cleansing of these parts essential. The contamination of the lesser peritoneal cavity is especially serious, as it is difficult to cleanse it properly, and efficient gauze drainage ought to be employed. It m[illegible] be best to drain through the back, as well as anteri[illegible]y.

Gunshot wounds of the stomach are frequently complicated with injuries of the lungs, diaphragm, liver, gall bladder, spleen, kidneys, pancreas, intestines and large vessels; hence, a high mortality follows, with or without operation. In the civil war four incised and punctured wounds of the stomach were observed, all of which terminated fatally. "One incontestable recovery from a shot perforation, a few recoveries from shot

wounds in the gastric region, in which the diagnoses were not determined unequivocally, and nearly 60 fatal cases of more or less complicated shot wounds of the stomach" were observed. In no case was suture employed. At my clinic, three patients with perforating stab and one with gunshot wound of the stomach have been operated on successfully, while two patients with gunshot wounds of the stomach, complicated with injuries to the spleen in one instance and perforation of the chest, lung, diaphragm and liver in another, died from shock and hemorrhage.

WOUNDS OF THE INTESTINES.

Owing to the large area occupied by the intestines, injuries to this part of the alimentary tract occur very frequently. It is difficult to understand how a bullet passing through the abdomen from before backward below the umbilicus can fail to perforate the intestines, yet this is sometimes the case. More often the bowels are perforated in a number of places. As has been said, the oblique and transverse passage of a missile through the abdominal cavity is attended with the greatest damage to the viscera. A careful search should be made for intestinal perforations; if the course of the bullet is known, only those parts in the immediate vicinity of the wound may require to be examined; if the course is unknown or is doubtful, the whole intestinal tube may have to be carefully searched. When the perforations are found, they should be closed with silk or catgut sutures; if the wound is small, it may be inverted by a purse-string suture; if large, it must be closed by some of the various forms of intestinal sutures. When there is much loss of substance, the rent should be sutured transversely to the lumen of the gut in order not to narrow unduly the lumen of the tube. When there are several openings in close proximity to each other, a resection of the intestine may be required. Care should be taken to prevent undue exposure of the viscera. The peritoneal cavity is usually more or less contaminated with fecal discharges, but this does not always occur if the operation is not too long delayed. In every case a careful toilet of the peritoneum should be made, the exposed parts washed off with salt solution, and, in my opinion, gauze drainage employed. Injuries of the large intestine are attended with a lower death rate than those of the small. A number of cases of undoubted gunshot wounds of the large intestines recovered during the civil war, while few, if any, such lesions of the small gut were survived. Of twelve patients with gunshot perforations of the small intestines, many of them complicated with other injuries, operated on in my service, 50 per cent. recovered. One patient with stab of the ascending colon recovered, and one with gunshot wound of the rectum and bladder died. I have had no case of perforation of the gall bladder, but I imagine the proper treatment would be cholecystectomy. Of 20 cases occurring in my service, in which the hollow viscera were perforated, 55 per cent. of the patients recovered after laparotomy and suture.

WOUNDS OF THE SOLID ORGANS.

Injuries to the liver and spleen occur occasionally without lesions of other organs, but usually in conjunction with traumatisms of neighboring structures. The danger in these cases is chiefly from hemorrhage, which is frequently very great. Bleeding may be controlled by suture in some cases or by packing the wound with gauze; or, in the event of the spleen being disorganized, it may be removed. The pancreas is seldom injured, but when it is lacerated the danger is great.

The kidneys may be injured by gunshot or stab, either without peritoneal penetration or with it. Lesions of these organs require exploration, packing, suture or nephrectomy, in accordance with the nature and extent of the injury found.

WOUNDS OF THE PELVIS.

Wounds of the pelvis, like those of the chest, are liable to involve the peritoneal cavity and to produce lesions of the pelvic viscera, notably of the bladder. The examples of gunshot wounds of the bladder, with retention of the bullet, are quite frequent, and require removal of the foreign body and the repair of the visceral damage. Extraperitoneal lesions of the bladder appear to be as fatal as those opening the peritoneal cavity.

HEMORRHAGE.

Hemorrhage is one of the most serious complications of intra-abdominal injuries and one of the most frequent. In gunshot wounds it does not occur so frequently as in cutting lesions, unless some of the great vessels are lacerated. In a case of stab of the ascending colon herewith reported, the bleeding could not be arrested until the aorta was compressed. The report of a remarkable double perforation of the aorta, in which the patient survived five days and two hours, I also append to this paper.

SUMMARY OF CASES.

The following summary includes all patients treated by me and my assistants, but does not include patients treated by my surgical colleagues at the University Hospital:

Total number of undoubted penetrating wounds of the abdomen treated, 29. Cases in which laparotomy was not done, 5; of which, one patient receovered, 20 per cent., and four patients died, 80 per cent.

Penerating wounds of the abdomen, in which laparotomy was done, 24; of these, 15 patients recovered, 62.5 per cent., and 9 died, 37.5 per cent.

Penetrating wounds of the abdomen, with perforations of the hollow viscera, 20; 11 patients recovered, 55 per cent., 9 died, 45 per cent.

Gunshot wounds with perforation of the hollow viscera, 16; 7 patients recovered, 43.75 per cent., 9 died, 56.25 per cent.

Stab wounds with perforations of the hollow viscera, 4; 4 patients recovered, 100 per cent.

Penetrating wounds in which various lesions were found, but without actual perforations of the hollow viscera, in which laparotomy was done, 4 patients, all of whom recovered.

While the cases here enumerated are too few to prove much, they are nevertheless suggestive—without operation 80 per cent. of the patients died; with operation, 62.5 per cent. recovered.

CASES OF PENETRATING WOUNDS OF THE ABDOMEN IN WHICH LAPAROTOMY WAS DONE.

GUNSHOT WOUNDS.

Case 1.—Pistol wound of the small intestines, suture of four perforations, subsequently traumatic aneurism of circumflex iliac artery. Recovery.

Patient.—P. D., white, aged 60, was admitted to the University Hospital, Dec. 22, 1893.

Examination.—He was not seen by me until eighteen hours after he was shot. The ball entered the abdomen four inches above Poupart's ligament, and about the same distance to the inner side of the anterior superior spine of the ilium, and passing through the ilium, was found under the integument of the right buttock. He was not shocked, temperature 101, pulse 104.

Operation.—An incision was made through the track of the bullet. Considerable liquid blood and blood clots were found in the peritoneal cavity, and some feces and foreign bodies. These were removed, and the exposed parts flushed with hot water. There were four perforations of the ileum, near the ileocecal valve, three being small, while the fourth was an inch in length, horizontal in direction and with widely everted edges. All the openings were sutured, the largest opening being closed transversely, to avoid any undue narrowing of the gut. Gauze was packed into the incision.

Result.—The patient did well for nearly three weeks, when a pulsating lump, which proved to be a traumatic aneurism, of the deep circumflex iliac artery, was discovered in the right iliac fossa. An incision above Poupart's ligament exposed the vessel in its continuity; it was ligated, and the man made an uneventful recovery.

Case 2.—Pistol wound of abdomen, four perforations of ileum. Death.

Patient.—A white man, aged 30, living in Virginia, was shot about 6 p. m. on Nov. 20, 1894. He was placed on a steamboat and brought to Baltimore, reaching the hospital about 8:30 the next morning, or fourteen hours after receiving the injury.

Examination.—At this time he was suffering from general peritonitis, the abdomen being distended, and rigid, with pain, tenderness and regurgitant vomiting present, pulse 160, and temperature 103. The bullet had entered the right side of the abdomen between the umbilicus and the anterior superior spine of the ilium.

Operation.—In the absence of Dr. Winslow, Dr. Spruill performed laparotomy at the site of the bullet wound, finding blood, feces and lymph extravasated in the peritoneal cavity, with agglutination of the intestines. Four holes were found in the ileum, which were closed, the belly flushed out and the incisions sutured. He died sixteen hours later.

Autopsy.—At the autopsy, the bullet was found embedded in the psoas muscle, and all the perforations closed and water tight. The intestinal canal was full, which doubtless was the cause of the rapid peritonitis.

Case 3.—Gunshot wound of the stomach. Recovery.

Patient.—S. W. R., white, aged 58, was admitted to the University Hospital on July 4, 1895. He was shot with buckshot fired from a small cannon by some boys who were on an elevation. A shot struck him in the left side, just below the apex of the heart, and passed into the peritoneal cavity. He vomited blood with clots.

Operation.—He was operated on probably within two hours. The perforation was found on the anterior surface of the stomach, from which gas escaped, but no extravasation of food had occurred. The opening was closed, and after the excision of the discolored edges of the bullet wound, the incision was sutured. He made a good recovery in one month.

Case 4.—Pistol wound of the abdomen; six perforations of the small intestine. Death.

Patient.—E. J., colored, aged 25, was admitted to the University Hospital on September 8, 1895. He was shot about 10 p. m., and reached the hospital an hour later.

Examination.—There was a bullet wound of the abdomen, four inches above Poupart's ligament, and two inches to the left of the median line. The skin was blackened with powder, showing that the pistol had been held almost in contact with the body.

Operation.—At midnight laparotomy was done. The incision was made in the middle line, extending from the umbilicus to the pubes. Five perforations of the ileum were found and three of the mesentery, and there had been but little hemorrhage and no escape of intestinal contents. The perforations were closed and the cavity flushed out. The abdominal walls were very rigid. The patient took the anesthetic badly, and went into a condition of collapse, hence the operation was hurried.

Result.—The patient died of peritonitis four days later, and an undiscovered perforation was found in the angle of junction of the ileum with the cecum The other perforations had healed firmly. The bullet was found in the cecum. This man's death was due to the overlooking of a perforation, and is greatly to be regretted.

Case 5.—Gunshot wound of the abdomen; seven perforations of the small intestines and one of the sigmoid flexure. Death.

Patient.—B. F. T., white, aged 66, was shot on Sept. 2, 1896, and was admitted to the hospital within an hour. The ball entered the right side of the abdomen.

Operation and Result.—A median laparotomy was done, about two hours after he was shot. Seven holes in the small intestine were sutured, and a search not revealing any further wounds, the abdomen was closed. He was not shocked by the operation, and seemed to be in a favorable condition for recovery. Vomiting of blood soon set in, the cause of which I am at a loss to understand. He died on September 3, and the coroner said that the sigmoid flexure was torn and that the No. 38 bullet lodged in the left side of the sacrum. I do not know whether or not the man died of peritonitis.

Case 6.—Pistol wound of the liver, small intestine and mesocolon. Recovery.

Patient.—S. T., colored, aged 12, was shot with a pistol on Sept. 4, 1897, at 5 p. m., and was admitted to the University Hospital five hours later. The bullet had entered the abdomen, slightly to the right of the middle line, and about midway between the ensiform cartilage and the umbilicus.

Operation.—Laparotomy was done at 11:30 p. m., the incision, four inches in length, passing through the bullet wound. The bullet had passed through the lower border of the liver, traversed the transverse mesocolon, and wounded the jejunum in five places. The intestinal wounds were ragged, with everted edges, and liquid feces escaped from the openings. The perforations were closed, the intestines cleansed, gauze packed over the openings in the liver, and strips of gauze allowed to protrude from the wound for drainage. The patient was brought from the country, a distance of 10 miles. He made a prompt recovery.

Case 7.—Pistol wound of small intestines. Recovery.

Patient.—E. A. B., white, aged 44, was shot on Sept. 6, 1897, at 3 p. m., and was admitted to the hospital one hour later.

Examination.—A bullet wound was found one inch to the right of the middle line, and one inch below the navel.

Operation.—The incision passed through the bullet wound, and revealed six ragged holes in the small intestines and one through the great omentum. The perforations were sutured with mattress sutures, closing the openings in a transverse direction to the lumen of the gut. This man was very adverse to an operation, and required considerable persuasion before he would consent. Gauze drainage was employed. Recovery took place, but for some days after operation he was very ill.

Case 8.—Pistol wound of duodenum. Recovery.

Patient.—T. F., colored, aged 23, was shot with a pistol on Sept. 14, 1897, at 11 p. m., and was admitted to University Hospital at 9 a. m. the next morning. He also had been brought from the country, in fact, from the same place as the patient in Case 6, 10 miles distant. The bullet had entered the abdomen on the right side, at about the tip of the eleventh costal cartilage.

Operation.—Operation was done eleven hours after the injury. The incision was made in the right linea semilunaris, eventually extending from the costal arch to the pelvis. The peritoneal cavity was filled with dark blood, bile and intestinal fluids, which had gravitated even into the pelvis. A large ragged wound, about an inch in length, was found in the upper part of the duodenum, from which fluids exuded freely. Owing to the deep situation of the injury, it was very difficult to suture the perforation, but it was finally accomplished, two rows of Lembert sutures being placed. The peritoneal cavity was flushed with hot sterile water, and carefully mopped out, and a glass drainage tube was placed between the stomach and liver, and another in the pelvis, and gauze was also packed into these parts. The middle of the incision was sutured, and the upper part left entirely open with the gauze protruding. Contrary to expectations, the patient did well, his highest temperature being 100, pulse 90. The bullet, a large conoidal one, was voided at stool on the sixteenth day.[1]

Case 9.—Pistol wound of small intestine. Death.

Patient.—W. D., white, aged 27, was shot on Oct. 1, 1897, and was brought at once to the hospital. The patient, a stout, short and flabby man, had been shot in the left side of the belly, the bullet entering about two inches below and to the left of the umbilicus.

---

[1] I exhibited these last three patients at the same meeting of the Clinical Society of Maryland, all of them being on stretchers.

Operation.—Median laparotomy was performed two hours after injury, and five perforations of the small intestine and three of the mesentery were found and sutured. The patient took the anesthetic badly. Subsequently he complained of much pain and vomited frequently. Death occurred on the third day.

Autopsy.—Stitches were intact; there was some plastic peritonitis, but no purulent infection and no perforations had been overlooked. He seemed to have died of acute sepsis.

All the preceding cases, with the exception of Case 2, have been published in detail in the *Annals of Surgery*, vol. xxviii, p. 487, and are presented in abstract here.

Case 10.—Pistol wound of abdomen and thigh. Recovery.

Patient.—W. V. W., white, aged 43, was admitted to University Hospital on Dec. 18, 1898.

History.—While seated in a buggy, he attempted to place a heavy Colt's Navy revolver in an inside pocket of his overcoat, when the hammer of the pistol caught in the torn lining of the pocket and the weapon was discharged. The 38-caliber bullet went downward and penetrated the abdomen about an inch above Poupart's ligament, and passing through the flexed thigh, was found embedded in the cushion of the carriage seat. This occurred at 8:30 a. m., and I saw him almost immediately and sent him to the hospital.

Operation.—He was pale from apprehension, but was not greatly shocked. He was operated on one and a half hours after injury. The wound of entrance was quite large, that of exit very small. An incision was made parallel with Poupart's ligament, and the track of the bullet explored. It descended behind the ramus of the pubis, escaping the external iliac vessels, and emerged from the pelvis at the obturator foramen, and then passing through the thigh emerged about the gluteal fold. I did not think the peritoneal cavity had been penetrated, but concluded to do a median laparotomy and to search for lesions. On opening the abdomen, there was no evidence of injury to be noted until I passed a piece of gauze, held in a long forceps, into the left side of the pelvis, which showed fecal stains, when it was withdrawn. A loop of the ileum was now pulled up and a rent about one inch in length was found, located near the mesenteric border of the gut. This was sutured with a double row of Lembert sutures and securely closed. The pelvic cavity was wiped out, all blood clots being removed, a large glass drainage tube inserted and the incision closed down to the tube. A strip of gauze was also placed in the track of the bullet for drainage. The after-history is quite uneventful, his temperature was afebrile, the drainage tube was removed on the fourth day and he left the hospital in three weeks cured.

Case 11.—Pistol wound of the thorax, penetrating abdomen, and passing through the stomach and liver. Death.

Patient.—K. O'N., white, female, aged 30, was admitted Christmas night, 1899.

History.—Shortly before coming to the hospital she was shot by a man, the pistol being held close to her body. The bullet entered the left side of her thorax, in the anterior axillary line, and ranging downward, fractured the seventh rib, opening the pleural cavity, and passing through the lung and diaphragm, entered the peritoneal cavity, passed through the liver and both walls of the stomach, and lodged in the left psoas muscle.

Operation.—Laparotomy was done at once, and a wound on the anterior surface of the stomach, near the point of entrance of the esophagus, was sutured with difficulty. It was believed that another wound was present on the posterior wall of the stomach, but it could not be exposed. There was considerable bleeding from the liver and other injured structures, and she was markedly shocked. Gauze was packed above and below the stomach. In spite of free stimulation, she did not react from the depression and died twelve hours later.

Case 12.—Pistol wound of the stomach and spleen. Death.

Patient.—F. S., colored, aged 23, was admitted on the night of Sept. 27, 1898.

History.—While attempting to escape from a policeman, he was shot in the left side over the spleen, between the eighth and ninth ribs, the ball passing through the spleen and into the stomach at its great extremity, causing a wound an inch in length in the wall of the stomach.

Operation.—Laparotomy was done at once, and the lesions mentioned discovered. The stomach was filled with undigested food, which had escaped into the greater and lesser peritoneal cavities. The wound in the stomach was sutured, with great difficulty, the peritoneal cavity cleansed as well as possible, and the incision left partly open, with gauze protruding from it for drainage.

Result.—When the patient was returned to the ward, my assistant elevated the end of the bed, as there was a condition of shock. The next day a loop of small intestine protruded from the wound and was replaced; whether this had any influence in causing his death I do not know, but he died in collapse within twenty-four hours.

Autopsy.—At the autopsy the perforation was found closed and the bullet lodged in the stomach.

Case 13.—Pistol wound of stomach and intestines. Death.

Patient.—A. T., colored, aged 44, was admitted to the hospital on Nov. 6, 1900. The ball had entered the epigastrium and passed through the walls of the stomach and then passing downward, penetrated the small intestines in many places and lodged under the skin of the buttock.

Operation.—Laparotomy was done, and the holes in the stomach and small intestines sutured. There was much extravasation of stomach and intestinal contents, which could not be thoroughly removed. Gauze packing was employed. Peritonitis promptly supervened and the man died in two days. The operation to repair the injuries in this case was very extensive.

Case 14.—Pistol wound of the abdomen, involving the small intestines, bladder and rectum. Death.

Patient.—R. M., colored, aged 25, was shot in the lower part of the abdomen, and the bullet ranging downward, passed through a loop of the ileum, making two openings, and then perforated the bladder and the rectum.

Operation.—These perforations were sutured, that in the rectum being difficult to reach. Pneumonia supervened, probably from the anesthetic, and he died in a few days. This case also occurred in November, 1900.

Case 15.—Rifle shot of the stomach, jejunum and sigmoid flexure. Death.

Patient.—L. H., white, aged 15, was admitted to the hospital Christmas day, 1901. He was shot with a rifle at Savage, Md., four hours previous to admission, and was brought about 30 miles to the hospital.

Operation.—Laparotomy was done at once, and two perforations were found in the stomach, two in the jejunum and one in the sigmoid flexure; these were sutured, the peritoneal cavity cleansed of blood and fluids. The patient did badly, vomiting set in, and symptoms of peritonitis supervened, of which he died in forty-eight hours.

Case 16.—F. B., Italian, aged 26, was admitted to hospital on Christmas day, 1901, a short time after the previous patient. He was shot with a pistol at Skyesville, Md., about 35 miles distant, at 10:30 a. m., and reached the hospital at 6 p. m. The bullet, No. 38, entered on the right side of the left lumbar region. His belly was rigid and he complained of much pain. The bladder was emptied and the urine was normal in appearance.

Operation.—An eight-inch incision was made by my assistant, Dr. A. A. Mathews, through the left rectus muscle. On opening the peritoneal cavity, a loop of small intestine at once presented in the incision, having two perforations, which were sutured, and a systematic search was made of all the intestines and viscera, and another perforation was discovered in the jejunum, which was closed, and the whole cavity flushed with hot normal salt solution. Drainage was established with gauze packing. The patient made a prompt and uneventful recovery.

Case 17.—Pistol wound of the abdomen. Recovery.

Patient.—W. K., white, aged 16, was shot with a pistol by a negro boy, at a distance of 12 to 15 feet, on Nov. 20, 1904. The bullet entered one and one-half inches above the anterior superior spine and three inches to the right of the umbilicus.

Operation.—An incision was made at the wound of entrance and the peritoneal cavity opened. The missile grazed the cecum, making a contusion, but no perforation, and then passed through the posterior layer of peritoneum and lodged in the muscles. The contused area was turned in with sutures, the cavity cleansed and drainage established. Some suppuration occurred, but the boy made a good recovery.

STAB WOUNDS.

Case 18.—Stab wound of both walls of the stomach. Laparotomy. Recovery.

Patient.—Mrs. M., white, aged 53, was admitted to the hospital on Nov. 23, 1896, with a stab wound of the abdomen.

Examination.—The wound was one-half inch in length, situated near the middle line and 3 inches below the ensiform cartilage. The patient was much shocked, the pulse rapid and weak and the extremities cold.

Operation.—A transverse incision, including the stab wound, was made across the abdomen, and at once the odor of beer was perceived and particles of partly digested vegetable matter were found loose in the peritoneal cavity, with blood clots. The bleeding wound was found on the anterior wall of the stomach, the vessels were tied and the openings closed with Lembert's sutures. The great omentum was torn through, the posterior wall of the stomach exposed and a wound similar to that on the anterior surface was found and closed. The abdominal cavity was mopped out and then flushed with hot sterile water and the incision was closed without drainage. Highest temperature was 99.4 and pulse 96. She was discharged well in six weeks. The operator in this case was my associate, Dr. St. Clair Spruill.

Case 19.—Stab wound of ascending colon. Recovery.

Patient.—G. L., white, aged 27, huckster, was admitted to the hospital Dec. 14, 1899, with a stab wound midway between the ribs and the crest of the ileum on the right side.

Operation.—At my request, Dr. H. M. Fitzhugh performed laparotomy and found the ascending colon penetrated in three places and partially cut in another place. There was a furious hemorrhage, the source of which was not determined, nor could it be controlled until the aorta was grasped and prolonged compression made. The wounds in the intestines were sutured, blood clots removed and the abdominal incision closed.

Result.—He was much shocked and required normal salt infusion. The after-course was not smooth, infection of the abdominal wall occurred and much sloughing, but he gradually recovered, withstanding also a sharp attack of pneumonia.

Case 20.—Stab wound of left side, severing the cartilages of the lower ribs and penetrating the stomach. Recovery.

Patient.—J. W. P., white, aged 32, brakeman, was admitted to the hospital on Nov. 2, 1897, at 10:30 p. m. One hour previously he was stabbed in the left hypochondrium, the cartilages of the costal arch being severed and the omentum protruding.

Operation.—Immediate laparotomy was done, the protruding omentum reduced and an incision into the stomach closed with silk sutures. The contents of the stomach had not escaped, and the abdominal incision was closed. The after-history is uneventful, and he made a prompt recovery.

Case 21.—Stab wound of abdomen, severing costal cartilages. Recovery.

Patient.—J. W. R., colored, was admitted to the hospital Oct. 26, 1897. While engaged in an exciting discussion in the country, he was stabbed in the belly and came to the hospital twelve hours later.

Examination.—The injuries were almost a counterpart of the preceding case, except that the knife did not penetrate so deeply and the stomach was not cut. He had a cut 3 inches long in the left hypochondrium, severing the costal cartilages, and penetrating the peritoneal cavity. The omentum was protruding from the wound and was liberally covered with iodoform, and the parts were filthy.

Operation.—The belly was thoroughly cleaned and the protruding omentum excised. An incision was made and the stomach and other structures examined without finding any further lesions. The man made an uninterrupted recovery, and I had the pleasure of exhibiting him and the preceding case together at a meeting of the Clinical Society.

Case 22.—Stab wound of the stomach. Recovery.

Patient.—A man was admitted to the hospital Oct. 6, 1901, at 3 a. m.

Examination.—He was very much shocked and had two punctured wounds of the chest wall, which did not penetrate the pleural cavity, and one just below the costal border on the left side, about 2½ inches from the middle line. This wound penetrated the anterior wall of the stomach, which was distended, but the posterior wall escaped injury.

Operation.—He was stimulated with strychnia, and 700 c.c. normal salt solution were injected. A long incision was made on the left side through the left rectus muscle, and a large quantity of blood rushed out. There was also considerable extravasation of the stomach contents into the peritoneal cavity. A cut one inch in length was found in the stomach, from which the mucous membrane protruded as a rosette. Two arteries were spurting and were ligated, and the perforation was closed with three rows of sutures. Large quantities of clotted blood were removed from the dependent portions of the peritoneal cavity. The omentum and intestines were washed off, the cavity flushed with hot salt solution and gauze tucked in every direction for drainage. Although the patient was in a very critical condition, recovery ensued. This patient was operated on by my assistant, Dr. A. A. Mathews.

Case 23.—Stab wound of the abdomen, made with scissors. Recovery.

Patient.—A man about 54 years of age, a voluntary patient at the Sheppard and Enoch Pratt Hospital, on account of melancholia, was taking exercise with an attendant, and saw a large shears in a stable. Before he could be stopped, he pulled up his vest and stabbed himself five times in the abdomen. This occurred about 3 p. m. on Nov. 1, 1902. He had no sooner inflicted, as he supposed, fatal injuries, than he became possessed with an urgent desire to live.

Examination.—I reached him about 6 p. m., and found him pale and somewhat shocked and very repentant. There were five punctures in the upper and middle parts of his abdomen, from which blood was escaping.

Operation.—Laparotomy was done at once, under difficulties, and it was found that two of the punctures had penetrated the peritoneal cavity, and that one puncture had also cut the stomach, perhaps not entirely through. This incision was sutured, blood removed from the abdomen, the wounds disinfected as well as possible and gauze drainage employed. He made a good recovery, and his melancholia disappeared as soon as his convalescence became assured, and he continues well to the present time.

Case 24.—Stab wound of abdomen. Recovery.

Patient.—Italian, aged 21, was stabbed in the right side of the belly at Havre de Grace, Md., on May 28, 1905. He rode some distance to a physician's office, carrying his intestines in his hand. The physician enlarged the wound and returned the intestines and sewed up the skin with silk sutures. More than twenty-four hours later he was brought to the University Hospital, a distance of 36 miles.

Operation.—The abdomen was thoroughly cleansed, the wound opened and enlarged, and a careful examination of the intestines made. A marked peritonitis was already present. The intestines were agglutinated with each other and there was some foreign matter in the peritoneal cavity. There was a partial cut in the small intestines and in the mesentery. The intestines were washed off, drainage with gauze instituted and recovery progressed rapidly.

CASES OF PENETRATING GUNSHOT WOUNDS OF THE ABDOMEN IN WHICH LAPAROTOMY WAS NOT DONE.

Case 25.—Pistol wound of abdomen. Recovery.

Patient.—J. C., colored, aged 29, received a wound from a pistol of small caliber, fired from some distance. The ball entered the abdomen one and one-half inches below the umbilicus, making a small circular hole, through which the omentum protruded.

Treatment.—A drainage tube was inserted, ice bags applied externally and opium administered internally. He was discharged well in one month.

Remarks.—This occurred in 1881, immediately before Sim's lectures on this subject, and was the first case of penetrating wound of the abdomen that came under my care. Probably no visceral lesion was sustained.

CASE 26.—Pistol wound in epigastrium and of right forearm, causing compound fracture of the radius. Death five days and two hours after injury.

Patient.—S. P., negress, was shot by her husband with a 32-caliber revolver.

Injury.—One bullet fractured the right radius, the other penetrated the epigastrium, one and one-half inches to the left of the linea alba and three inches below the ensiform cartilage. From the location of the wound it was thought that either the stomach or transverse colon was perforated. The patient had no vomiting of blood or bloody stool, had pain with tympanites at the point of injury, but no elevation of temperature. No operation was performed. She lived five days and two hours.

Autopsy.—No peritonitis was found. There was no perforation of any of the viscera. Some liquid blood was in the abdominal cavity, and the peritoneum was extensively raised by an enormous blood clot under it. The bullet had passed entirely through the aorta, below the celiac axis, making a slit in its anterior surface and an everted counter opening, and had then entered the body of the third lumbar vertebra. It seems almost incredible that a person could live more than five days, with two bullet holes in the aorta.

CASE 27.—Pistol wound of small intestine, with 25 perforations and 2 in bladder. Death in eighteen hours.

Patient.—C. W., white, on June 3, 1884, was shot in the hypogastric region, with a large pistol; he then turned and received another wound in the buttocks.

Injury.—The bullets pursued a nearly parallel course, and one lodged under the skin of the abdomen an inch from the first wound, while the other was found under the integument behind, three inches distant from the posterior wound. He was admitted at night, pulse good and shock not marked, urine bloody. When seen by me the next day he was in collapse, pulseless, vomiting, and in great pain.

Autopsy.—The peritoneal cavity was filled with blood, feces, pepper pods, and cherry stones. The lower portion of the small intestines for about six feet was riddled, there being twenty-five holes in the gut, one in the mesentery and two in the bladder.

CASE 28.—Pistol wound of the liver. Death in eighteen or twenty hours.

Patient.—D. G., colored, was shot on the same day as the last two mentioned patients, and like these with large-sized pistols.

Injury.—The wound was on the right side, in the anterior axillary line, and about two inches from the nipple. The ball entered the fifth intercostal space, and ranging downward, fractured the sixth rib and entered the abdomen between the sixth and seventh ribs. Much bleeding and marked shock followed, with pain in region of wound and in the right shoulder. No bile escaped from the wound. The contents of the stomach were vomited, but no blood. The patient did not rally from the profound shock, and died on the same day.

Autopsy.—The bullet passed entirely through the upper surface of the liver, and was found embedded in the substance of the diaphragm. Peritonitis was beginning.

CASE 29.—Pistol wound of back; perforation of the small intestine in two places. Death in twenty-nine hours.

Patient.—W. G., colored, aged 34, was shot by a policeman from whom he was trying to escape. The man was running, and was about 15 feet distant from the officer. The weapon used was a large-sized Smith & Wesson revolver. The ball entered one inch to the left of the second lumbar vertebra. Seven hours after the injury the pulse was 82, respiration 32, and temperature 98.8, and there was no shock. Soon pain about the umbilicus set in, with muscular rigidity, vomiting, and also an alvine evacuation of blood. Urine was passed voluntarily and was not bloody. There was numbness of the left thigh in the area supplied by the anterior crural nerve. I was anxious to perform laparotomy on this man, but was overruled by superior authority. Peritonitis supervened rapidly, and the patient died in twenty-nine hours from the time of injury.

Autopsy.—The ball had entered the peritoneal cavity from behind, pierced the small intestine in two places and finally dropped into the pelvis. Feces had escaped and an intense general peritonitis was set up.

There are here 5 cases of penetrating abdominal wounds, with one recovery and four deaths.

No operation was done on any of these patients, and the mortality was 80 per cent., which corresponds pretty accurately with that computed by Otis. Would the mortality have been less under operative treatment? The first patient would probably have recovered if the belly had been opened, as recovery occurred spontaneously, and the fifth patient would have had excellent chances for recovery. It is possible, but not probable, that the case of perforation of the liver might have been saved if gauze packing had been made use of to arrest bleeding. It is not probable that the patient with 28 perforations of the small intestine and bladder could have been saved by any treatment. Nor is it any more reasonable to expect a cure after a double perforation of the aorta. In my opinion, however, all of these patients should have been subjected to laparotomy.

DISCUSSION.

DR. CHARLES M. COOPER, San Francisco, referred to two incidents that came under his observation during the late South African war. The first relates to a patient who had been shot in the abdomen, in whom no exit wound could be found. Unsuccessful efforts to locate the bullet had been made and the *x*-ray used. Prof. John Chiene, when shown the patient, remembered the golden rule—"examined the rectum"—and found the bullet, thus emphasizing the importance of not forgetting old methods of diagnosis. The second relates to a physician who had been shot in the abdomen, and who recovered without operation. In reply to an inquiry as to his opinion of the main factor responsible, he said he had vomited the day before he was shot and had eaten nothing afterward. Subsequent to his injury he continued to refuse food, and thus applied to himself the well-known starvation treatment of acute abdominal diseases that is associated with the name of Dr. Ochsner. This principle, Dr. Cooper believes, should be enforced in the treatment of patients who are not operated on, care being taken to keep the mouth and fauces as clean as possible and to prevent the swallowing of saliva.

DR. FLOYD McRAE, Atlanta, Ga., said that physicians in the South see more pistol wounds than do physicians in the North. He said that in exceptional cases suturing the bowel in a transverse direction to prevent contractures is the best thing to be done. In this way there is produced an infolding which is particularly obstructive and a tendency to separation of the edges of the wound. Suture in the longitudinal direction should be the rule. Dr. McRae has seen some cases in which the bowel was separated from the mesentery where it was not considered of much importance, but later there was perforation and death. The mesentery is the only means of blood supply to the intestine, and if it is separated a fatal result will certainly occur later. This condition calls for a resection of the bowel. In the toilet of the bowel physicians used to use gallons of water and had a larger mortality than now. It is only in exceptional cases that general lavage of the peritoneal cavity is advisable. The non-exposure of the viscera is a very important point in technic, and the man who follows the intestines carefully without exposure will have a lower mortality.

DR. DEFOREST WILLARD, Philadelphia, said that one point of importance is the question of excessive handling. If the physician is unable with a dry toilet to do good work, posterior drainage will be an exceedingly valuable addition and will save some lives.

DR. JOHN B. BOUCHER, Hartford, Conn., said that his experience with recent gunshot wounds of the abdomen leads him to believe that drainage is a decided disadvantage. He believes in sewing each perforation as he finds it, making as thorough an examination with as little exposure of the viscera as possible, and after careful sponging, closing the peritoneal cavity tight. By this means better results will be obtained than by drainage, which unquestionably lowers the resistance of the peritoneum. No chance should be left for external contamination.

Dr. R. Winslow said that handling the intestines is not good practice, if it can be avoided. As to washing out the peritoneal cavity, if there has been but little contamination, certainly not, but if there has been a great deal of soiling, as for example, with beer, food, feces, etc., plenty of water should be used. He is convinced that these cases should be drained.

THE DENTISTRY OF TO-MORROW.*

HARRY P. CARLTON, D.D.S.
SAN FRANCISCO.

Several years ago I had the opportunity to read before the Odontographic Society of Chicago a paper on "University Training and Dental Education," in which I took the ground that dentistry would only be a full profession and recognized as such when the character of the men who comprised it brought its recognition up to what it should be; that as this increase in dignity and professional status must come from within the body of the profession itself, a high grade of young men must be added to its ranks. I outlined the demands of the day and the way to meet those demands, making a plea for better educated material with which to begin our dental training, claiming that with these superior men we could shut the doors of our profession against the trifler and the tinker, and reserve the training of our schools for those who brought to the work the instincts, traditions and outlook of the scholar; the result, real doctors of dental surgery.

I look on this occasion and this paper as but another chance to express my thoughts, to take another step forward, and to prophesy what seems to me the inevitable outcome. If dentistry is to continue to advance, along what lines must it go? It is pretty well conceded that mechanically we are close to the top notch, and only moderate advance can be looked for in that direction. The advance must then be along scientific lines, higher education and the encouragement of research and investigation.

Dentistry is a specialty of medicine, but the only specialty not universally requiring the degree of doctor of medicine. Indeed, dentistry should be one of the most important branches or specialties of medicine, for in the mouth begin all those processes of nutrition and metabolism which of recent years have attracted so much attention. Thus far neither the physician nor the dentist has given enough scientific study to this special area of the human anatomy, and neither knows what the other has been doing or learning or is doing and learning.

Medicine and dentistry, though cognate sciences, have always been separately studied. This disassociation is now seen to be a great error, due not alone to the fact that the relation of the mouth and teeth to the rest of the anatomy was not understood, but also because only the mechanical aspect probably appealed to those who first considered the matter; no doubt dentistry had its beginning in the pulling of a tooth. This conception of dentistry as an entity and not as an integral part of medicine has made it an art, possibly a trade, rather than a science. A correct appreciation of physiology, pathology and bacteriology—physiology representing the normal relation between the mouth and the rest of the alimentary canal; pathology showing the relation between the deranged functions of the mouth and abnormal conditions of other portions of the alimentary system; and bacteriology as an outgrowth of the study of pathology, showing the causes of the pathologic conditions of the mouth—necessitates an entirely different attitude and is rapidly bringing the child, dentistry, back to its real parent, medicine. It has been said that "Dental science has brought the diseases of the mouth, jaws and teeth so obviously under the domain of general pathology, that somatic problems elsewhere presented in the body are best and easiest studied in the mouth."

The opportunities of modern dentistry are so new and vast that not only is more manipulative skill demanded, but ampler education, more insight, more sagacity, faculties to whose development nature and elaborate training must both contribute. And this training must be given under the guidance of scientific teachers, non-practitioners, men of productive scholarship, men who devote their lives to the special work of teaching the various subjects which are embodied in a medical education, instead of by those who give instruction during the intervals of a busy practice.

There are new duties calling for a high degree of disciplined intelligence; to quote a recent article, "The knowledge of life and disease represented by the average D.D.S. degree is certainly deplorably deficient." How are we to remedy this? Give our young men a thorough medical training. Dentists are specialists only in their own handiwork, but the ground work is uniform and the demand for individualized education emphasizes the whole difference in our chosen tasks and ignores the great similarities. The technic of our branch of the profession, then, appears only as a small variation of the work in which we all share. The higher the level on which professional specialization begins, the more effective it is. And, again, "The higher the profession, the more nearly is the whole man working in every act and the more, therefore, is a broad general education necessary."

How well I remember Professor Joe Le Conte's likening of the modern system of education to the great sequoia, in which the primary and secondary schools were the rootlets and roots, the college culture courses the great bole, and the coming out from it at various altitudes as specializing branches, were the group of professional schools that make up the university. The trunk thus dividing grew higher and smaller, but persisted as the principal member all the way, until the topmost reach of pure culture was highest of all. Specializing without culture he likened to the low-branching bush, with no hope of reaching any fair height, and that the great branch of this tree of knowledge that deals with the study and care of the human body should spring from the main trunk after a considerable height of culture, at least that of the college curriculum, which Dr. Le Conte likened to the unbranching trunk, was the contention made in the former paper already mentioned. Without this no standing among the learned professions can be had at all. The half-light of the forest depth can not be grown out of at any less altitude.

It is equally clear, also, that the great branch, the study of the human frame I have spoken of, must go out from the culture trunk of the university tree as a whole. The least consideration of its logical relations to the general culture and to other branches of knowledge will show the justness of this statement. And, having thus gone out from the main trunk, there is plenty of room for a considerable outward and upward reach of this great branch before it begins to subdivide into the various specialties, as the care of the various portions of the human body. So viewed, the mouth has as much relation to medical science, as a whole, as has the care of the eye, the ear, or, indeed, any other organ or group of organs.

---

* Read in the Section on Stomatology of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

He would be a superficial reasoner who would deny the great culture value of the medical course. Dr. Le Conte himself found it a firm foundation in its hold on physics and chemistry and a whole group of other sciences, and yet more in its cultivation of the habits of scientific observation of facts and logical reasoning from them for the stately structure of his own scientific attainments. The man who has taken it is a doctor, with none of the weakening qualifications of D.D.S., connoting a lesser scientific rank.

Most dental schools of the present time are at the mercy of the demands of the day and age, and their students are the product of the surroundings, not the choice of the school. An ideal professional school would be one that exists for its work alone, for scientific investigation and practical instruction not given by busy wage earners.

The dentist of to-morrow can not be the same sort of man as the dentist of the past, whose own little sphere has been bounded by thirty-two teeth. He must be the carefully educated student in the medical branches, plus the dental specialties, and you can only make him so by following the same educational plan as in preparing the doctor of medicine. Without the requisite medical education, the ordinary mechanically expert dentist is not competent to practice his profession—he can only exercise a mechanical dexterity, but with the proper education he not only exercises the same dexterity, but he has professional ability.

The mouth is a fairly good barometer of the whole system, but your merely mechanical man, as contrasted with the dental specialist in medicine, is not competent to read it, and he does not. Why? How can any man untrained in medical science understand the problems presented to him in the condition of the mouth? We all know how exceedingly often some affection of the mouth or teeth is but an indication of a general systemic disturbance of metabolism; and, on the contrary, how frequently we see a faulty dental anatomy causing nutritive derangements which are puzzling to the physician who is ignorant of the large part played by the mouth in general alimentation. These things can not be comprehended by the merely mechanically trained dentist, as distinguished from the dental specialist, any more than they are intelligible to the physician whose training has omitted all reference to the mouth as a vital part of the alimentary canal. He who would in the future confine his professional work to conditions involving the mouth and teeth—the dental specialist—must be a broad diagnostician; he must know the relation of the mouth to the general system and he must interpret what he sees in the mouth in the light of his general medical education.

To bring about this condition—a condition which must surely come with the passage of time—the same preliminary training in the academic sciences will be required, whether the student intends to practice general medicine or surgery, or to specialize along the lines of ophthalmology, dermatology, orthopedic surgery or dentistry.

The same general medical education must also be required, no matter to what special region of the anatomy nor to what special line of work the student intends to confine himself eventually.

What will be the results of this medical education? When this is accomplished what is going to become of your dentist? Practical life demands a division of labor; therefore, the specializing of the individual. There will be a division of the product just as in general medicine, and the natural ability of the individual will show itself. Some are going on plugging teeth, but better able, not less equipped for that work, for this higher education is not a question alone of preparing great men for great things; it must also prepare little men for greater things than would otherwise have been possible. Another lot are going to take up broad scientific work and research—not merely the mouth, but the mouth as merely a part, and the world will be spared from lots of trouble. But he who takes up the mechanical side of dental medicine has a broad and an inviting field of work before him. Thus far the orthopedic surgeon and the ophthalmologist who confines himself to refraction are most highly skilled mechanical specialists in medicine, but the medical dentist of the future will stand with them.

Consider the remarkably high degree of mechanical skill developed in the proper adjustment of a plaster jacket! Think of the tremendously complex Wullstein apparatus, devised for this purpose, and consider a man with no mechanical skill, in spite of any amount of medical education, attempting to apply such a jacket!

Dentistry, as well as orthopedic surgery, requires this highest kind of mechanical ability—take the apparatus used in orthodontia, for example; its construction and application call for the best mechanical skill, but they need back of that the academic training, or they don't reach the elevation. The real professional man should possess the resources of a highly developed, reasoning faculty, which comes only after years of systematic pursuit of what might be called higher or university study. It is this broad mental training that makes better dentists and better men. We are not only professional wage earners—we live for our friends and our nation; we are in contact with nature and science, with art and literature; we shape our town and our time. Let us, then, provide the kind of men who know how to think.

Imagine a profession of mere operators; professional men! Not so; mechanical artisans. The hope of the profession lies not in fitting a system of instruction to the capacity of unpromising students, not in "substituting intellectual milk for intellectual meat, aye, even in giving this milk in small quantity because of the puniness of the babes; but in choosing students equal to the requirements of an advanced method of instruction and substituting capable men for the class that now fill our colleges."

Turning out men with broad, well-balanced minds, with the faculty of judgment, strengthened by the mastery of principles rather than the acquisition of information. So much of the groundwork of medicine and dentistry is held in common that it is a wasteful folly to teach it in separate schools rather than in one well-equipped and well-manned institution. The cutting out of this unnecessary duplication of work is the spirit of the age and the method of much that we call our modern advance.

To summarize this point: The things that are purely ground work, physics, inorganic chemistry, and all the branches that make for the building up of the man able to see clearly, to imagine vividly and to reason correctly, as Dr. Henry Van Dyke puts it—these should be given in college. Then, all the studies necessary to the understanding of the human anatomy, physiology and hygiene should be taken in a medical course; then, and then alone, is it time to specialize on oral surgery to make a dentist. It used to be said of Cuvier that, given a single bone, he could construct a whole animal, but he never arrived at that point by the study of one kind of bones only. Rather it is the method of to-day to study the whole skeleton, yes, and all the other parts of an animal as well, in order to understand one bone.

"Great truths approach slowly and dwell a long time with small minorities." Progress is the law of this American race, which stands for all that's best; truly it is a race which knows no rest. Was it not Macaulay who said, "A standing point which was yesterday invisible is the goal to-day and will be the starting post of tomorrow?"

WHAT WILL PROBABLY BE THE DENTAL EDUCATIONAL STANDARD FOR THE COMING DECADE?[*]

CHARLES C. CHITTENDEN, D.D.S.

MADISON, WIS.

At the last meeting of this Section, at Atlantic City, in 1904, a symposium on dental educational standards was read, which was exhaustive and thorough in its character. In a paper presented at that symposium I had the honor to report chronologically the various facts as they had transpired, during the current year, concerning the attitude of the individual dental schools and the National Association of Dental Faculties toward the newly inaugurated four years' college course.

It had become apparent that a large number of the smaller and financially hampered schools were determined on returning to the three years' course.

This Section, at that time, in its discussions, expressed, in no uncertain terms, its entire disapproval of any such retrograde action.

Immediately following the meeting of this Section came the annual meeting of the National Association of Dental Faculties at Washington, D. C., where the whole subject was gone over and discussed very exhaustively, with the final result that, by a close vote of twenty-four to twenty-one colleges, the four years' course was upheld. This occurred in the early part of June. Almost at once following the adjournment the *ad interim* committee began to receive the resignations from membership in the National Association of Dental Faculties of a number of schools which were opposed to the decision at Washington to continue the four years' course. These resignations created such a panic in the ranks of the colleges that the *ad interim* committee was finally induced to call a special meeting of the National Association of Dental Faculties to be held at St. Louis, July 18, 1904, whose sole purpose should be a reconsideration of the final decision made at Washington, the month previous, to continue the four years' course.

At this special meeting there were, of the fifty-one colleges in membership, twenty-eight represented. By a vote of 26 to 2 (being by a majority of one of the total membership) the four years' course was revoked and a three years' course of thirty weeks in each year was adopted in its place. The public announcement of this distinctly retrograde step (taken by a bare majority of one of the membership of the college association) came as a distinct shock to the rank and file of the profession. There was no semblance of an off-set in the way of increased standard requirements for admission to the college course to, in some measure, soften the baldness of the action. The outside world was simply made suddenly aware that the National Association of Dental Faculties, without waiting to graduate a single class or man under the vaunted higher educational system which that body had spent at least three years in elaborating, and had then declared to the world as absolutely necessary to properly fit the student for the dental degree, had, without explanation, struck its colors and surrendered. The one saving phase of the whole transaction was the fact that practically one-half of our colleges had been opposed to the change and had only acquiesced in it "to save the Faculties Association."

The examiners of the United States had been loyally standing behind and ready to protect the schools in their higher standards in every way. To them this bold retrogressive step called for immediate action. A blow had been struck, for commercial reasons only, at the established standards, and struck, too, by our National Association of Dental Faculties! All the schools of the better class had been obliged to yield to the inevitable and lower their standards—all save one, whose noble independence but makes the situation appear the more pathetic.

The annual meeting of the National Association of Dental Examiners was held late in August, 1904, at St. Louis. It was apparent, from the first news of the "retrogression," that something must be done to retrieve the situation before the world, and the examiners rose at that meeting to the occasion. The following report from the committee on colleges, preceded by a careful résumé of the entire situation, was unanimously adopted:

> Your committee would therefore recommend that this association establish at once, to go into operation not later than the opening of the school year of 1905-6, the educational requirements, for admission to the dental college course, of graduation from an accredited high school or its full equivalent, all examinations of credentials and equivalents to be placed in the hands of an acceptable appointee of the state superintendent of public instruction where not otherwise provided for by law.
>
> In view of the present disturbed and unsettled conditions existing in dental educational circles, and with a belief in avoiding all unnecessary disturbances of standards at this time, your committee would further recommend that no change be made at this time in the present requirements of this association of not less than 28 calendar months of college attendance for graduation.

By what had occurred the trust of the examiners in the ability of the college association to maintain good faith under certain exigencies was so badly shaken that all standing resolutions which in any way interfered were rescinded, and the committee on colleges was instructed to prepare a new list of recommended colleges, based on the acceptance by the individual schools of the standards declared in the above report. The work was to be done independently of the National Association of Dental Faculties.

After having spent many months in correspondence and careful conferences with many of our ablest teachers and scientists, the committee on colleges issued the following letter to the deans of this country, Feb. 14, 1905:

---

[*] Read in the Section on Stomatology of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

> In consideration of the conflicting views as to dental educational standards which have existed for some time, the National Association of Dental Examiners at its annual meeting held at St. Louis, August, 1904, deemed it expedient, and necessary for the upholding of such schools as sought to maintain the standards already published to the world as the minimum that should obtain, to declare what educational standards should be required by the state boards of examiners as a criterion of reputability of the schools seeking recognition of their output.
>
> This *ad interim* committee, which is also the committee on colleges, was instructed to inform all schools of the action taken, and directed to prepare a recommended list of colleges on the basis of the standards established at that meeting.
>
> Feeling fully the gravity of the duty imposed, this committee has expended much effort in striving to arrive at a basis of fairness to all interests concerned, in carrying out its general instructions. The chief requirement established at St. Louis was that of "graduation from an accredited high school or its full equivalent" for admission to the classes of 1905-6.
>
> In several schools and university departments this requirement is already in actual operation, and our committee finds a considerable number of other schools desiring to maintain it. All these, of course, will be placed on the recommended list. There are, however, other schools whose deans assert that to enforce at once this advance requirement would work a serious financial injury to their institutions.
>
> The question of what would constitute a proper length of course for graduation from a dental college has always been left by the examiners to the colleges themselves, except that, after a school has announced to the public a certain course as necessary to properly fit a student for graduation, if it, for private or financial reasons, deliberately lowers its requirements in any particular, the question of good faith and reputability of that school becomes at once a matter for adjudication by every board in the country.
>
> We, therefore, acting on authority of, and, *ad interim*, representing the National Association of Dental Examiners, which is the advisory body of the various state boards in their official acts, respectfully request that you authorize the committee on colleges to place your school on the recommended list of colleges by the acceptance of the following educational requirements for students, viz.:
>
> For matriculation or registration, "graduation from an accredited high school or its full equivalent, all examination of credentials and equivalents to be placed in the hands of an acceptable appointee of the state superintendent of public instruction where not otherwise provided for by law," said requirements to be inaugurated not later than the beginning of the school year of 1906-7; and a college course for graduation optional with you of either four years of seven months each or three years of nine months each, this course requirement to be inaugurated the present year, *1905*.
>
> It is to be expected that schools maintaining these standards will be protected in so doing by the several boards composing the National Association of Dental Examiners.
>
> It is the intention of this committee to prepare and to publish the recommended list of colleges not later than April 1 next, in order to give all schools the earliest opportunity to announce these standards to the public. Therefore information as to your decision is desired as early as possible.
>
> Very respectfully yours,
>
> Committee on Colleges.

The responses have been quite general and, on the whole, unexpectedly satisfactory. It developed that a large number of schools were only too desirous for the establishment of an educational requirement at once reasonable and at the same time so sufficiently advanced as to not only retrieve the unfortunate back step of 1904, but also to place their schools on a permanent working basis so advanced as not to be liable to material change for several years to come. As one dean expressed it, "This higher standard places us in a position to go ahead with our business, and we will not have to change again unless the Faculties' Association goes one better. It has been this uncertainty as to what was coming or what we were going to do next that had troubled me most. Now I feel as though we had something definite before us."

And thus it has happened that, up to this date, the acceptances have far outnumbered the refusals and the new college list is still growing.

The *rationale* of the matter being that while the National Association of Dental Faculties may and has set minimum bounds of requirement for its members, it can not and never will undertake to prohibit any or all of its membership from placing their individual requirements as much higher as they may see fit. The only chance taken by the individual school in so doing is as to the ability of its product to compete successfully in the market with that of the schools retaining the lower standards.

The question, therefore, resolves itself to this: Will the examiners, with the power of law behind them, keep faith and redeem the pledges made by their authority and in their name by their chosen representatives, i. e., stand by and judicially maintain the advanced educational requirements established by the National Association of Dental Examiners at St. Louis in 1904?

The faith manifested by more than a score of our foremost schools and universities in the integrity and honor of the examiners in this respect would seem to be a harbinger of a new order of things which will be, at least, paramount to commercial success in the conducting of educational institutions.

If the hopes herein foreshadowed shall become realities, a new impetus will be given to dental education, a better class of minds will be attracted to our schools, and for many years to come there will be no further disturbance in preliminary educational requirements for entering our dental colleges.

DISCUSSION.

Dr. F. L. Platt, San Francisco, said that a degree from a university is certainly commendable and necessary, but he thinks that it is hardly all that is required. A large part of dentistry is mechanical and must necessarily continue to be so. He believes that in addition to a university degree, if a young man is going to study dentistry, he should also attend a school of manual training. Dr. Platt has noticed that the students who have had some manual training do superior work. There must be a combination of these two kinds of training before one can become a good dentist. After a man has gained a knowledge of chemistry, physics, bacteriology and therapeutics, his training should be largely clinical. The greater part of dentistry can be taught by clinics, and Dr. Platt believes that each member of a class should be required to demonstrate his ability in the presence of others, and should not wait to learn to do this after he has acquired a degree. Experience in teaching operative technic has convinced Dr. Platt that so far as operative work is concerned, clinical instruction is far ahead of the lecture. He does not believe that dental colleges should be private corporations. Schools of law, medicine, theology and dentistry should be integral parts of state universities, with funds provided by the state and faculties paid by the state. At the end of the first six months, if a student does not display aptitude for the work, he should be advised to take up something else. Dr. Platt agreed with Dr. Carlton that a high school education is not sufficient. Dr. Platt attended a pedagogic meeting a year ago, and heard many people speak who were in favor of a four years' course in dentistry, but did not hear a single sound argument in its favor. He thinks that the course should be at least nine months a year and four years if necessary, but to make the course four years at the expense of cutting down the length of each year, is not advancing. Students who have five months' vacation will not graduate from college as well equipped as students who have only three months' vacation. Some argue that the students get so tired they need five months' vacation. Others argue that students ought to have five months to work to earn money to finish their course. Neither of these arguments is worth considering. If the course is to be lengthened, let it be made four years of nine months each. A plan could be adopted requiring a degree in arts and letters for admission, as well as a manual school training, and then three years of good, earnest work would turn out good dentists.

Dr. M. L. Rhein, New York, said that possibly the colleges that have a six months' course are in the South, and they would have a six months' course whether it was three years or six. It has always seemed difficult to get southern colleges to give any lengthy term. The tendency in the northeast has been to increase the teaching term whatever the number of years. Dr. Rhein thinks the basis for dental education should be absolutely as high as that of medical education, and until that standard is reached dentists are below their true standard, and that is the only thing that keeps dentistry from being recognized as it should. It is the one thing that keeps students of the proper caliber from taking up this specialty. They do not care to place themselves on a lower plane than any of the other branches of medicine. This section should strive to make the requirements of dental education as high as that required for medicine, and to keep them up to that standard. Dr. Rhein thinks it impossible for a man to practice this branch of medicine without being thoroughly grounded in general medicine. The groundwork of medicine is recognized as being not only of value but of necessity, and while dentistry is a technical work, and while a technical school is of the utmost importance, without the scientific knowledge of medicine the dentist is at a loss to properly apply his technical knowledge.

Dr. A. H. Levings, Milwaukee, said that there are many subjects in the medical curriculum which would be of no use to the dentist, though a dentist must have some knowledge of the fundamental branches, such as chemistry, pathology, bacteriology, histology and therapeutics. He must have some knowledge of surgery and perhaps a smattering of medicine, but Dr. Levings thinks that the study of neurology, gynecology, obstetrics, dermatology, otology and allied subjects would be of no benefit to the dentist commensurate with the time spent in study. If the coming dentist were required to take a full course in medicine, he would have to spend an extra year in mechanical work, because the medical student's time is fully occupied. He can not complete the course of to-day in less than four years of eight or nine months each. Dr. Levings said that he has heard many say that the requirements should be put so high that but few dental students could meet them. The only consideration should be what is best for these prospective dental students. Dr. Levings appreciates as much as anyone that the more culture, refinement, education and mental training an individual has, the higher he can rise in his profession, and the more easily he can maintain himself, but it is not within the possibility of every prospective dental student or every prospective medical student to secure the standard. Such a course as is given now in dental colleges will train any man who has a high school education so that he can master all the problems pertaining to either dentistry or medicine. Those who have the time and money may take a medical and a dental degree, and before this an A.B. degree, and polish themselves as much as possible.

Dr. M. I. Schamberg, Philadelphia, said that it may take some time before dentists will reach a higher standard than that existing at the present time. To his way of thinking, there are two things of prominent importance in taking up this subject: one is the raising of the standard of the profession, and the second, which he considers even more important, is the placing of such men in the dental world as are able to render the best possible service to humanity. The financial status of the dental college should be absolutely ignored. It may be that the work of the stomatologist and the dentist will ultimately become separated before arriving at the desired goal. If that be the case, it will probably be best for humanity at large. Dr. Schamberg would prefer to see the various dental institutions under the control of state universities, so that the financial side of the question would not enter into it so much as the educational.

Dr. G. V. I. Brown, Milwaukee, said that in this question of dental education a distinct advance of some kind is wanted. The purpose of Dr. Chittenden's paper is to fulfill the crowning act of a long life that has been given freely to the upraising of the standard, that before he dies something definite may be accomplished in the establishment of a higher standard of dental education. Dr. Brown said that he drew the resolution in the faculty association regarding the four-year term, and he has made more or less of a battle at different times for the four-year course. It is useless to discuss at this time the value of such a course because for the time at least it has been decided to be inadvisable. He believes that the additional year could be secured with less hardship to the schools and with more likelihood of its being practical than any other advance. He believes every argument that has been made about the mechanical side of dentistry, and that since there can not be a four-year course there ought to be higher entrance requirements, and that the course should be at least nine months, or as near that length as possible. Dr. Brown is connected with schools in the South and in the West. He sees both sides of the question, but at the present time no plan has been suggested which is practicable for meeting the situation. When some one presents a plan which will carry with it a distinct advance, so long as it is an advance which will enable the colleges of the South, West and elsewhere to continue and to prosper, that plan will meet with approval, and when that time comes he has no doubt the examiners' and faculty associations will again be on a harmonious basis. Dr. Brown believes in the value of having dental colleges under state control, but even under this condition it is not all smooth sailing by any means. At this time it seems nothing beneficial can be accomplished by discussion alone.

Dr. H. P. Carlton said that he has never yet written a paper of this character nor spoken his thoughts along this line, that the discussion did not at once turn to the question of courses and years. He wants to establish foundation courses and to leave the length of courses and curricula out of the question. He hopes to live to see it proved that the dentist of the future is going to be a medical man. The more a man gets in brain development the better dentist he will be. A man can not be too broad and too scientifically trained to be a dentist.

RECENT PROGRESS IN MATTERS OF WATER SUPPLY AND SEWAGE DISPOSAL.[*]

GEORGE W. FULLER, C.E.

NEW YORK CITY.

Of the various topics in this branch of sanitation there is none which has received so much discussion during the past year as that of the proposed use of copper sulphate. This chemical has been proposed for various purposes, the chief of which are as follows:

1. As an algicide; 2, as a germicide for infected water supplies used without subsequent filtration for drinking; 3, as a germicide for the effluent of coarse-grained sewage filters prior to entering drinking water streams; 4, as a germicide in conjunction with a coagulant in the filtration of highly polluted streams.

COPPER SULPHATE AS A GERMICIDE.

Although copper sulphate as a germicide and disinfectant has been studied from time to time for many years, especially in Germany during and after the se-

vere outbreak of cholera in 1892, this question has recently pressed forward for attention, largely due to the very interesting bulletin prepared by Dr. Moore and Mr. Kellerman[1] and issued in May, 1904. A second bulletin by the same authors was issued in April, 1905, and it appears from it that more than fifty reservoirs and ponds have been treated during the past year with copper sulphate to remove various forms of algal life producing objectionable tastes and odors.

---

[*] Read in the Section on Hygiene and Sanitary Science of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

To repeat these various experiences is needless here, in view of their having been detailed elsewhere and summarized in the more important instances in the last bulletin referred to.

When attention was directed to this matter last year, as is usually the case under such circumstances, public opinion varied widely in regard to it. On the one hand, were those who approved and supported the proposition most cordially and were inclined to regard it as a cure-all, while, on the other hand, were those of a more dubious frame of mind who were uncertain as to whether with ordinary care the copper sulphate might not become so unequally distributed in the water as to become injurious to the people drinking the treated water, and who were somewhat skeptical as to the ability of this chemical to kill vegetable life, at least under some conditions.

As a result of various experiences, copper sulphate as an algicide now appears to be viewed somewhat more favorably than it was a year ago. When water infested with algæ is to be filtered carefully after treatment, the process appears safe, provided the copper sulphate is applied uniformly in small proportions and is precipitated by the water.

When copper sulphate is applied to waters used for drinking purposes without being filtered following the treatment, a number of eminent professional men have felt disposed to advise against its use until further information concerning it is available. This position seems to be a conservative and prudent one ordinarily to adopt at this time.

Doses of copper sulphate of one part in from 1,000,000 to 10,000,000 parts of water usually suffice to kill algæ. Sometimes the doses are much more dilute, and in a few instances the strength must be about one part per 100,000.

It is not clearly understood into what form the chemical is converted when applied to various waters. Also uncertain in the minds of some is whether or not the passing of an abnormally large proportion of the copper from the reservoir in a relatively small portion of water is due to disturbances of the precipitated copper.

In this review it is needless to discuss more or less conflicting evidence on a variety of topics allied to this subject. It is sufficient to point out that opinion is not harmonious to a satisfactory degree on the following points:

(a) Toxicity to man of copper sulphate and salts in quantities encountered under various conditions.

(b) Chemical reaction of copper sulphate with constituents of various waters.

(c) Immunity and stimulation of other vegetable growths.

(d) Effect of copper sulphate on various fish.

(e) Disposal of copper under varying conditions of application.

COPPER SULPHATE AS A GERMICIDE FOR UNFILTERED WATER SUPPLIES.

This use of copper has been widely studied in the laboratory and has been put into practice in a number of places where public water supplies are known to be of unsatisfactory quality and where high death rates from typhoid fever prevail. Some misunderstanding in regard to this subject has occurred, and the general public in a number of communities appears to have gathered the impression that copper sulphate applied with this end in view serves as a substitute for filtration. Evidently this is not the view of the government officials who have looked into this matter, as they claim that the process is applicable in places where filter plants have not yet been built, and where during the period of filter construction unfiltered water of a dangerous character is supplied to the consumers.

Another aspect of this same matter is, of course, the use of copper vessels, such as canteens, etc., for obtaining water free from objectionable germ pollution.

It is very clear that copper sulphate can not serve as an adequate substitute for properly constructed and properly operated filtration works. In the case of adequate filters giving poor efficiency due to improper supervision, it is debatable whether, other things remaining equal, copper sulphate would or could be used so as to insure better results. Where filter works do not now exist, the feasibility of this treatment may be considered. This also applies, perhaps, to the treatment of water in this way in small receptacles.

It seems to be the consensus of opinion of quite a number of prominent sanitarians that a final opinion on this proposition of using copper sulphate as a germicide for drinking waters without subsequent filtration ought to be deferred until available data are more complete and trustworthy than they are at the present time. When this condition of affairs is reached it is not probable, in my opinion, that there will be material differences of opinion among experienced sanitarians.

Laboratory data on typhoid germs artificially cultivated for comparatively long periods do not necessarily afford a reliable criterion as to the quantity of the copper sulphate required, nor the period of contact necessary in order to effect, or even to approach, sterilization under conditions of practice. Depleted vitality in this connection may quite likely be of as much importance here as it is in species determinations. Laboratory data, furthermore, are seriously involved by questions of osmosis and other features which, independent of the copper sulphate added, in laboratory experiments cause typhoid and other germs to die more quickly than can be relied on in practice.

Concentrations of from 1 in 100,000 to 1 in 50,000 seem necessary for sterilization of infected water. Experiences such as those recorded at Columbus, Ohio, by the city health officer and summarized in the last bulletin of the U. S. Department of Agriculture do not seem to cover sufficiently the various essential facts to entitle them to great weight. In fact, I am certain that there are many reasons for believing that in the experiences with the city water supply of Columbus too little is recorded of the actual condition as to infection of the treated water and also of the prevalence of typhoid fever after the treatment ceased to justify the conclusion that doses of copper sulphate of less than 1 per million actually destroyed typhoid fever germs in a few hours.

---

[1] Bulletins Nos. 64 and 76 Bureau of Plant Industry of Department of Agriculture.

COPPER SULPHATE AS A GERMICIDE FOR THE EFFLUENT OF COARSE-GRAINED SEWAGE FILTERS.

Since it is now a well-established fact that coarse-grained sewage filters, more frequently spoken of as contact beds and sprinkling filters, are capable of producing at fairly high rates of filtration effluents of a non-putrescible character, sanitarians have given more or less thought to the question of the hygienic significance of such effluents, since it is known that they do not remove disease germs with such thoroughness as intermittent sand filters. Further, as these sewage filters seem to be the only ones available in some sections of the country, where porous layers of sand or gravel are not to be found, the sterilization of these partially purified sewages is a matter which doubtless will receive attention in the future. At present little need be said other than that the process is a somewhat expensive one, according to investigations at the Sewage Testing Station at Columbus, Ohio, by Messrs. Johnson and Copeland. They find that to kill typhoid germs in sewage effluents it is necessary to make an application of about 1 in 50,000, the cost of which at current prices is in the neighborhood of $8 a million gallons.

The composition of the sewage with reference to alkalinity and organic matter, temperature and period of contact are more or less important matters which require further elucidation. The applied copper salts in these proportions produce a noticeable precipitate, the deposition of which requires consideration.

COPPER SULPHATE AS A GERMICIDE IN CONNECTION WITH FILTRATION.

At Anderson, Ind., during the past winter, copper sulphate was applied to the water just prior to filtration and in conjunction with sulphate of iron and lime as coagulants. These experiments were made for a comparatively short period with a new filter plant, the construction of which was not at that time fully satisfactory in all particulars. The investigations were conducted by Professor Burrage on behalf of the city, and Mr. C. Arthur Brown, representing the contractors for the filter plant and also the American Steel and Wire Company, which places sulphate of iron on the market in large quantities. Several other bacteriologists and chemists were present, including representatives of the United States Department of Agriculture. The claims made of the beneficial result in killing bacteria by adding minute quantities of copper sulphate, such as 1 in one million parts of water or less, do not harmonize with a considerable amount of information obtained elsewhere. Especially inconclusive are tests for *B. coli communis* in 1 c.c. of water before and after filtration. Later tests have been made at a new filter plant at Marietta, Ohio, but the data are not yet available to the public. Still further tests are doubtless needed under a wide range of conditions before opinion on this phase of the subject may be safely reached.

WATER PURIFICATION.

Recent progress in this field has been confined largely to the application of the principles hitherto developed carefully along a scientific scale. It is highly gratifying to note that works are now being built for a number of the larger cities in this country, including Providence, R. I.; New Haven, Conn.; Hoboken, N. J.; Harrisburg, Pa.; Philadelphia, Pa. (partially completed); Washington, D. C.; Pittsburg, Pa.; Columbus, Ohio; Louisville, Ky., and quite a number of other smaller cities. Active steps toward securing filtered water also seem about to be taken at Cincinnati, Ohio; Toledo, Ohio; New Orleans; Troy, N. Y.; Wilmington, Del., and Minneapolis.

An interesting feature in connection with this subject is the number of reports made recently by prominent engineers in which filtration is advised of water supplies which a short time ago were regarded as of a quality not requiring filtration. The most prominent instance on record is that of the supply of New York City, where, as is well known, there has been an unusually low typhoid fever death rate for an American city for many years—since elaborate undertakings were made for the elimination of sources of pollution on the Croton watershed.

As to the extent to which filtered water from surface sources is now used in this country, reference is made to the important paper presented by Mr. Allen Hazen at the International Engineering Congress at St. Louis in the autumn of 1904. In the statistics therein presented, it is pointed out that in 1904, of an estimated population in the United States of 32,700,000 in towns and cities of more than 2,500 inhabitants, there are about 3,160,000, or 9.7 per cent., which are supplied with filtered water. Of this number, about 2,600,000 received water from mechanical filters, and the remainder, about 560,000, are supplied with water from sand filters. During the past four years, according to these statistics, there has been an increase of 70 per cent. in population supplied with filtered water, and this increase, from what has already been said with reference to large purification works now building or soon to be completed, will, no doubt, advance still more rapidly in the near future.

As still further indicating the extent of the present use of water filtration works, it was pointed out in the paper mentioned that, of all cities in the United States having a population of more than 25,000, there were 7.9 per cent. provided in 1904 with filtered water; 11.4 per cent. had filters under construction; 21.4 per cent. had filters either authorized or recommended officially; 31.1 per cent. had water of a sanitary character requiring either filtration or a new supply; 22.2 per cent. had water of reasonably satisfactory quality and probably not needing filtration for a long time, and 6 per cent. had water of good quality not requiring filtration.

There is no feature connected with water filtration of more interest to the sanitarian than the effect which these improvements in public water works produce on the health of the community adopting them. It is gratifying to note that a considerable proportion of the recently constructed filter plants are now operated in quite a satisfactory manner, while the larger ones are provided with superintendents possessing all the needed skill in chemical and bacteriologic technic. These more recently constructed filters, operated under intelligent supervision, have produced very marked reductions in the typhoid fever death rates in the communities in question, and, as pointed out in the paper by Mr. Hazen, they have affected also a material reduction in the general death rate. This latter feature is, of course, associated with quite a number of other factors, as is also true of reductions in typhoid fever death rates; but, generally speaking, it may be said that filtered surface waters in several communities have caused death rates to appear as low as in other communities similarly situated in which ground water of unsuspected character is supplied. Unquestionably, further investigation and elucidation are needed in order to establish clearly the significance of matters of water supply and sewage disposal with reference to vital statistics. In brief, how-

vere outbreak of cholera in 1892, this question has recently pressed forward for attention, largely due to the very interesting bulletin prepared by Dr. Moore and Mr. Kellerman[1] and issued in May, 1904. A second bulletin by the same authors was issued in April, 1905, and it appears from it that more than fifty reservoirs and ponds have been treated during the past year with copper sulphate to remove various forms of algal life producing objectionable tastes and odors.

To repeat these various experiences is needless here, in view of their having been detailed elsewhere and summarized in the more important instances in the last bulletin referred to.

When attention was directed to this matter last year, as is usually the case under such circumstances, public opinion varied widely in regard to it. On the one hand, were those who approved and supported the proposition most cordially and were inclined to regard it as a cure-all, while, on the other hand, were those of a more dubious frame of mind who were uncertain as to whether with ordinary care the copper sulphate might not become so unequally distributed in the water as to become injurious to the people drinking the treated water, and who were somewhat skeptical as to the ability of this chemical to kill vegetable life, at least under some conditions.

As a result of various experiences, copper sulphate as an algicide now appears to be viewed somewhat more favorably than it was a year ago. When water infested with algæ is to be filtered carefully after treatment, the process appears safe, provided the copper sulphate is applied uniformly in small proportions and is precipitated by the water.

When copper sulphate is applied to waters used for drinking purposes without being filtered following the treatment, a number of eminent professional men have felt disposed to advise against its use until further information concerning it is available. This position seems to be a conservative and prudent one ordinarily to adopt at this time.

Doses of copper sulphate of one part in from 1,000,000 to 10,000,000 parts of water usually suffice to kill algæ. Sometimes the doses are much more dilute, and in a few instances the strength must be about one part per 100,000.

It is not clearly understood into what form the chemical is converted when applied to various waters. ---

[1] Bulletins Nos. 64 and 76 Bureau of Plant Industry of Department of Agriculture.

nection with the testimony recently taken with regard to the litigation over the Chicago drainage canal, views are not as yet clearly crystallized. It is largely a question of time interval elapsing under various conditions of stream flow between the point of discharge of sewage and the withdrawal of the water for drinking purposes at points below.

Elaborate investigations made by Drs. Jordan, Russell and Zeit indicate that the life of typhoid fever germs may be somewhat shorter than has hitherto been considered to be the case. This, however, is still a debatable proposition, notwithstanding the general acceptance of the idea that various species of bacteria exert a more or less antagonistic influence in water on typhoid germs. Parchment sacks have in some ways improved the technic of these studies, but at Columbus, Ohio, Messrs. Johnson and Copeland have found apparently that these sacks when free from punctures do not prevent motile bacteria from passing through them.

Information from all sources, when plotted on a diagram, indicates that about 90 per cent. of typhoid fever germs in waters of various classes will live in decreasing numbers for periods ranging from 3 to 13 days, although it is quite uncertain how long the last 1 per cent. survives. Some of these bacteria undoubtedly live for a considerably longer period than one month.

There are about 90 sewage purification works of artificial construction now in existence in this country, and serving, as above indicated, a little over 1,000,000 population. Recently, on an average about half a dozen plants in large towns or cities have been constructed each year.

Based on practical experience and observation in the sewage purification field, and on observations made at considerable length at the Lawrence Experiment Station and elsewhere, it may be said that when porous sandy soil is available at small cost, this still appears to be the cheapest as well as the best method of purifying sewage. There are about 40 such plants now in existence in this country, serving a population in the aggregate of about 250,000.

The principal objection to sand filters is their clogging during cold weather, resulting then either in a material reduction in rate of filtration or in by-passing the filters entirely. It is as yet uncertain how far it is advisable to give sewage a preliminary purification before application to sand filters.

In the South and West, where porous sandy soil is not available, or in the East where it is expensive at suitable sites, it becomes necessary to consider other methods of filtration. The two principal types of coarse-grained filters are called contact beds and sprinkling filters. In each instance, they are composed ordinarily of fairly coarse material, ranging in size from about one-half inch to two inches. A contact bed is operated by filling the pores of the filter, letting the filter stand for a short period and then slowly draining out the sewage. Ordinarily the filters can be filled in this way three times daily, but from time to time they require resting. This method, particularly when double filtration is practiced, permits an effluent to be obtained which is non-putrescible and quite satisfactory for discharging into a stream. With sprinkling filters the unfiltered sewage is applied to porous material in the form of a spray, either from revolving sprinklers or nozzles set in satisfactory piping. If need be, sprinkling filters in cold weather can be operated as contact beds. The fact that spraying devices (sprinkling nozzles) did not freeze up at Columbus during the past winter is perhaps the most surprising feature to those who then visited the Columbus sewage testing station. This being so, it seems safe to say that with sprinkling filters rates of filtration several times as great as with contact beds may be used; that is, rates in the neighborhood of 2,000,000 gallons an acre daily. In some instances, this advantage of sprinkling filters can not be readily utilized, owing to inability to secure sufficient head for their operation without resorting to pumping.

The effluent of these [illegible] while non-putrescible, is not so free from bacteria as effluents of sand filters, and they are quite turbid. Much of this turbidity, however, can be removed by sedimentation for a few hours.

Clogging is a more or less serious factor in all filter beds for sewage treatment; in the sand filter, clogging material accumulates in small quantities year after year, and it appears that ultimately there is needed to be scraped a portion of the upper surface of the sand layer. Present indications are that coarse-grained filters, receiving a partially clarified sewage, will require the entire filtering material to be cleaned once say in from three to five years, or oftener, if excessively high rates of filtration are employed.

Generally speaking, the removal of suspended matter from the sewage before filtration is an economy, enabling higher rates of filtration to be used.

Chemical precipitation is not now adopted for new projects, owing to the expense both of chemicals and sludge disposal.

Septic treatment ordinarily is helpful, as it causes from 50 to 70 per cent. of the sludge to be deposited by subsidence. Of this deposited sludge about one-half can usually be disposed of by bacterial action. The tanks ought to hold at least from eight to ten hours' average flow. Covers generally do not assist septic action in proportion to their cost. With an adequate design and skillful regulation, objectionable odors need not be feared with ordinary sewages.

Where septic treatment is applied to domestic sewages, available evidence indicates that several years may elapse between periods of cleaning out the sludge. Where street washings and trade wastes enter the sewers, septic tanks may require cleaning once a year or oftener.

SEWAGE POLLUTION OF OYSTERS AND OTHER SHELLFISH.

Evidence from various sources indicates that sewage pollution of shellfish needs correction in many places, both for the welfare of the public health and for the interests of the oyster industry, which suffers from "oyster scares." Means for suitable regulation and control are a live topic for discussion among sanitarians.

When sewage comes from a small community and affects large shellfish interests, it seems reasonable to provide for adequate purification of the sewage. When the shellfish interests are small and the expense of sewage purification would be relatively great, it seems logical to remove the shellfish. Intermediate conditions require different treatment, depending on various local conditions, which is also true of a large number of sewage disposal problems.

DISCUSSION.

Dr. N. K. Foster, Sacramento, Cal., said that the question of water supplies and sewage purification to a person who is directly interested in public health is paramount to any other question. More preventable diseases can be traced to the water supply, and indirectly to the want of sewage purification, than to any other causes, barring, possibly, tuberculosis. The destruction of sewage in our state, California, comes more under ever, it appears that pure water is a sanitary feature of predominant importance, and there is no doubt about the substitution of a pure supply for an impure one having in repeated instances reduced the death rate to an extent practically unequaled by any other single sanitary improvement.

Nearly all recent improvements, both as regards sand filters and mechanical filters, refer to those features of design which relate, first, to means of securing a more reliable and automatic control of the process, and, secondly, to means of reducing the cost of operation, largely by the elimination of hand labor, due to improved mechanical appliances. In mechanical filters, this has come about largely through automatic regulating devices and the larger size of individual units, and in sand filters in devices for reducing the labor in cleaning the filters. In the latter, matters have advanced even so far as to the question of considering mechanical scrapers for cleaning the sand surfaces (Pittsburg).

Recently the city of Columbus, Ohio, situated in a section where the water supply, both from surface and ground sources, is very hard, put under contract a municipal purification plant of 30,000,000 gallons' daily capacity, which will not only filter the supply, but will also enable it to be softened. While there are many industrial softening plants in this country, and small town plants at Winnipeg and Oberlin, this is the first instance on record in this country where a large city has undertaken thoroughly to soften the water supply.

Much attention in the public press has been given to the recent method of treating the St. Louis water supply. This water, taken from the Mississippi river, has for many years been partially clarified by sedimentation in large open reservoirs. Early in 1904, as a preparatory step for the St. Louis Exposition, this water was further clarified in the same reservoirs with the aid of sulphate of iron and of lime as coagulants. In other words, the water was treated in a manner very similar to the treatment of sewage in the chemical precipitation works at Worcester and Providence and in many places in Europe. The result has been a far better clarified water than was the case previously. In fact, ordinarily the supply has been of satisfactory appearance.

Several statements by St. Louis authorities have appeared which indicate that this method is a complete and effective means of securing a water of satisfactory appearance and hygienic quality, and that filters are a superfluous institution. The facts do not warrant this position, as unquestionably filtration would improve the water supply of that city.

Sulphate of iron and lime in connection with filtration is a serviceable substitute for sulphate of alumina for some waters, but not for all. In some instances, the composition of the water makes it very difficult to guard against objectionable quantities of lime or of iron appearing in the filtrate.

PROGRESS IN WATER SUPPLY CONTROL.

There have been two steps taken in this country during the past year with reference to the control of water supplies which are of much interest to the sanitarian. T[illegible]st notable of these is the establishment of a [illegible]tment of health in Pennsylvania, with ample [illegible]ing to a higher grade of efficiency the sewer[illegible]vater systems in the various cities in that state. [illegible]s suffered quite severely for years from typhoid [illegible]t is gratifying, also, to note that the legisla[illegible]ennsylvania has made a reasonable appropria[illegible]arrying out these new laws in an efficient way so far as making it possible to provide a skilled staff of technical advisers and assistants is concerned.

growths.

(d) E

(e) D

applicat

The legislature of the state of New York also recently created a state water commission, with an appropriation of about $40,000. The object of this appears to be to investigate available supplies within the state with reference to seeing that there is an equitable arrangement made for the various large communities, including New York City, taking new supplies from sources well considered in the interests of all concerned. Projects for new supplies, it is understood, are required to be submitted to this state commission.

SEWAGE DISPOSAL.

I reviewed this branch of sanitation in its various aspects in a paper prepared on this subject for the International Engineering Congress held in St. Louis last October. In this paper it was pointed out that in towns of the United States of 4,000 population or over in 1900, of which there were 1,049, with a total population of about 28,000,000, there were about 20,400,000 people estimated to be discharging raw sewage into inland streams or lakes; about 6,500,000 discharged their sewage into the sea or into the harbors or tidal estuaries along the sea coast; while the remainder, about 1,100,000, were connected to sewage purification works.

As compared with most European countries, the population in this country is so scattered, the rivers are so large and the rainfall, for the most part, so much greater and more evenly distributed, that this relatively small proportion of sewage purification works indicates by no means that this country is so backward as some might seem inclined to think with reference to adopting purification works where they are clearly needed. There are, of course, quite a number of instances where sewage purification works are badly needed in this country; but, generally speaking, there are more efforts now being made toward the purification of the sewage of larger towns than has been the case hitherto. This is partly because of the status of local lawsuits and injunctions, and partly owing to the more adequate information now available indicating the best and cheapest way of purifying sewage under various local conditions.

Information on the subject of sewage purification still continues to be forthcoming each year from the important investigations which for 18 years have been systematically and uninterruptedly conducted by the Massachusetts State Board of Health at the Lawrence Experiment Station. In the annual reports of that board for the years 1902 and 1903 are especially valuable reports indicating the experiences not only with the various sewage purification works in that state, but also the conditions resulting from discharging the sewage of various cities under different degrees of dilution into neighboring water courses.

Generally speaking, it is found that nuisances are avoided when a stream provides a dilution during dry weather of about 3.5 cubic feet a second for the sewage of each 1,000 population connected with the sewers. Where manufacturing wastes are unusually extensive, it is sometimes necessary on small streams to provide a greater dilution than this to guard against nuisances. On large streams it is possible that this dilution may be slightly greater than needed in some cases.

As to that aspect of sewage disposal by dilution, which involves the question of infection of water supplies taken from streams a considerable distance below the entrance of sewage, it is to be stated that, while information has increased considerably, especially in con-

---

partment

nection with the testimony recently taken with regard to the litigation over the Chicago drainage canal, views are not as yet clearly crystallized. It is largely a question of time interval elapsing under various conditions of stream flow between the point of discharge of sewage and the withdrawal of the water for drinking purposes at points below.

Elaborate investigations made by Drs. Jordan, Russell and Zeit indicate that the life of typhoid fever germs may be somewhat shorter than has hitherto been considered to be the case. This, however, is still a debatable proposition, notwithstanding the general acceptance of the idea that various species of bacteria exert a more or less antagonistic influence in water on typhoid germs. Parchment sacks have in some ways improved the technic of these studies, but at Columbus, Ohio, Messrs. Johnson and Copeland have found apparently that these sacks when free from punctures do not prevent motile bacteria from passing through them.

Information from all sources, when plotted on a diagram, indicates that about 90 per cent. of typhoid fever germs in waters of various classes will live in decreasing numbers for periods ranging from 3 to 13 days, although it is quite uncertain how long the last 1 per cent. survives. Some of these bacteria undoubtedly live for a considerably longer period than one month.

There are about 90 sewage purification works of artificial construction now in existence in this country, and serving, as above indicated, a little over 1,000,000 population. Recently, on an average about half a dozen plants in large towns or cities have been constructed each year.

Based on practical experience and observation in the sewage purification field, and on observations made at considerable length at the Lawrence Experiment Station and elsewhere, it may be said that when porous sandy soil is available at small cost, this still appears to be the cheapest as well as the best method of purifying sewage. There are about 40 such plants now in existence in this country, serving a population in the aggregate of about 250,000.

The principal objection to sand filters is their clogging during cold weather, resulting then either in a material reduction in rate of filtration or in by-passing the filters entirely. It is as yet uncertain how far it is advisable to give sewage a preliminary purification before application to sand filters.

In the South and West, where porous sandy soil is not available, or in the East where it is expensive at suitable sites, it becomes necessary to consider other methods of filtration. The two principal types of coarse-grained filters are called contact beds and sprinkling filters. In each instance, they are composed ordinarily of fairly coarse material, ranging in size from about one-half inch to two inches. A contact bed is operated by filling the pores of the filter, letting the filter stand for a short period and then slowly draining out the sewage. Ordinarily the filters can be filled in this way three times daily, but from time to time they require resting. This method, particularly when double filtration is practiced, permits an effluent to be obtained which is non-putrescible and quite satisfactory for discharging into a stream. With sprinkling filters the unfiltered sewage is applied to porous material in the form of a spray, either from revolving sprinklers or nozzles set in satisfactory piping. If need be, sprinkling filters in cold weather can be operated as contact beds. The fact that spraying devices (sprinkling nozzles) did not freeze up at Columbus during the past winter is perhaps the most surprising feature to those who then visited the Columbus sewage testing station. This being so, it seems safe to say that with sprinkling filters rates of filtration several times as great as with contact beds may be used; that is, rates in the neighborhood of 2,000,000 gallons an acre daily. In some instances, this advantage of sprinkling filters can not be readily utilized, owing to inability to secure sufficient head for their operation without resorting to pumping.

The effluent of these coarse-grained filters, while non-putrescible, is not so free from bacteria as effluents of sand filters, and they are quite turbid. Much of this turbidity, however, can be removed by sedimentation for a few hours.

Clogging is a more or less serious factor in all filter beds for sewage treatment; in the sand filter, clogging material accumulates in small quantities year after year, and it appears that ultimately there is needed to be scraped a portion of the upper surface of the sand layer. Present indications are that coarse-grained filters, receiving a partially clarified sewage, will require the entire filtering material to be cleaned once say in from three to five years, or oftener, if excessively high rates of filtration are employed.

Generally speaking, the removal of suspended matter from the sewage before filtration is an economy, enabling higher rates of filtration to be used.

Chemical precipitation is not now adopted for new projects, owing to the expense both of chemicals and sludge disposal.

Septic treatment ordinarily is helpful, as it causes from 50 to 70 per cent. of the sludge to be deposited by subsidence. Of this deposited sludge about one-half can usually be disposed of by bacterial action. The tanks ought to hold at least from eight to ten hours' average flow. Covers generally do not assist septic action in proportion to their cost. With an adequate design and skillful regulation, objectionable odors need not be feared with ordinary sewages.

Where septic treatment is applied to domestic sewages, available evidence indicates that several years may elapse between periods of cleaning out the sludge. Where street washings and trade wastes enter the sewers, septic tanks may require cleaning once a year or oftener.

SEWAGE POLLUTION OF OYSTERS AND OTHER SHELLFISH.

Evidence from various sources indicates that sewage pollution of shellfish needs correction in many places, both for the welfare of the public health and for the interests of the oyster industry, which suffers from "oyster scares." Means for suitable regulation and control are a live topic for discussion among sanitarians.

When sewage comes from a small community and affects large shellfish interests, it seems reasonable to provide for adequate purification of the sewage. When the shellfish interests are small and the expense of sewage purification would be relatively great, it seems logical to remove the shellfish. Intermediate conditions require different treatment, depending on various local conditions, which is also true of a large number of sewage disposal problems.

DISCUSSION.

Dr. N. K. Foster, Sacramento, Cal., said that the question of water supplies and sewage purification to a person who is directly interested in public health is paramount to any other question. More preventable diseases can be traced to the water supply, and indirectly to the want of sewage purification, than to any other causes, barring, possibly, tuberculosis. The destruction of sewage in our state, California, comes more under the health authorities than the water supply. Unfortunately, the health authorities have nothing to do with that except to keep streams from being polluted. Any municipality can take their water as they see fit, or allow any private corporation to do it without any permission from the health authorities. That is an unfortunate condition, which Dr. Foster hopes sometime to see remedied. The same condition exists in a good many of the Western states. In the protection of streams the health authorities have considerable power, and in this work, bearing directly on the health as it does, more can be done than in any other direction. The protection of streams from sewage appeals directly to physicians and health officers, because they know that the typhoid rate is something alarming all through this country. If not a quarter of the typhoid cases are reported, as has been stated, and nearly all will admit that a large proportion are not, what a terrible condition there is, with the large number of deaths that result and the amount of suffering that pertains to that one disease, a disease which is absolutely caused by the carelessness and want of information of the people. In a recent inspection of one of the principal rivers in California, Dr. Foster found everything going into the stream, and when he brought to the attention of the authorities the fact that they were throwing their sewage into the stream from which others were drinking below, some of them felt that he was interfering with their personal rights. One man remarked that the streams were made for sewers, although that town was taking water out of the stream farther up and throwing their sewage back into the stream, where the neighboring towns below took it out. It is a question that ought to have prompt attention, and the health authorities should be given the power to control absolutely the disposal of sewage and also the water supply. The use of copper sulphate is another question that is of great interest. Dr. Foster is a little fearful of it unless it is under good control. A company in California is working on that system, and claims to be able to purify any reservoir. In one reservoir it is reported that the water is coming through colored. The copper may kill some germs and the algæ, but algæ are not the worst thing in water. If water is going to be poisoned with sulphate of copper, Dr. Foster asked if it is an improvement on the germs. The bacterial count in water treated with copper is certainly very low, probably a good deal lower than in most cities in the United States, but the gas-producing germs are still there, showing contamination. Whether or not the typhoid germs are there can not be determined, but Dr. Foster believes that they are. He thinks that physicians should go a little slow before giving full sanction to the copper sulphate method of treating water, and have it studied a little more. If irresponsible companies are promising to do these things and pointing to a scientific body of men as authority for it, it will lead to untold trouble.

Dr. M. L. Price, Baltimore, said that the effects of copper in small repeated doses have never been properly investigated. It may be of interest to those not acquainted with the fact that the oxygen-bearing pigment of the lobster's blood, corresponding to the hemoglobin of most animals and the chlorophyll of plants, is a copper instead of an iron salt. The modern sand filter beds for municipal water supply, and the contact and trickling beds for the disposal of sewage, mentioned by Mr. Fuller, are illustrated in the hygienic exhibit of the Massachusetts State Board of Health. All these methods of water supply and sewage disposal have been subjected to tests at the Lawrence Experimental Station, of which there is a model in the exhibit of the Section. Dr. Price said that he would be glad to demonstrate this exhibit to any one interested in water supply or sewage disposal.

Dr. C. V. Genoway, Spokane, said that in Spokane there is some trouble about sewage, and he wished to ask for information. The authorities in Spokane are about to spend about half a million dollars on water-works, and he has been asking them to pay some attention to the question of filtration. It has been talked of, but nothing has been done so far. They seem to think that the water is good enough without filtration, but the Spokane Valley above Spokane is becoming very thickly settled, and in the course of five years the river banks from Spokane to Coeur D'Alene City, about 30 miles, will be a continual town, and unless something is done now, some day there will be a frightful loss of life in Spokane. The new mayor, elected two weeks ago, has partly promised to listen on the subject of filtration. Dr. Genoway said that he knows little about filtration, but he wants to learn something about it, and to get what available literature he can on that line to show to the Spokane officials. When he went in office as health officer there were a large number of wells throughout the city. The water was cooler than the river water, that being the excuse people had for using the well. He looked up the records and found that typhoid fever had been prevalent, and on tracing it back he has found that at least 65 per cent. of the cases were caused by drinking well water; therefore, he is closing up the wells as rapidly as he can and compelling people to use river water. The sewage system in Spokane is not very satisfactory; that is, sewers empty into the river above the city and all through the city. Spokane started as a little town, and wherever the people found a convenient place to run the sewer water into the river they did so, and that Dr. Genoway is trying to have changed.

Dr. Denslow Lewis, Chicago, said in regard to conditions in Chicago that extensive bacteriologic determinations have been made by certain health officials of Illinois, with the result that the water supply of St. Louis is found to be improved. Now, there is an explanation, which is probably true. The increased volume of water going into the Mississippi since the construction of the drainage canal has diluted the sewage, favored oxidation, and, by increasing the flow of the river, has tended to lessen or to destroy bacteria. At all events, the statement has been made, and Dr. Lewis believes that it is true, that the water in the Mississippi at St. Louis is really better now than it was before the construction of the drainage canal in Chicago. The matter of first importance is to have a pure and adequate supply. All cities can not, like Portland, have snow-clad mountains in their vicinity, nor can they all have spring water, but the endeavor should be made to have the supply pure and to have it adequate. Failing in that, the next thing is to see that the water is purified one way or another, as is now done in many cities. Dr. Lewis was surprised at the statement that in Columbus, Ohio, the first attempt at public filtration had been made, as he had always understood that Philadelphia had a public filtration plant which had proved very successful. In Chicago, the work is not yet done. The drainage canal is completed, but still many sewers empty into the lake. There has been under construction for years a system of intersecting sewers, the idea being to have all the sewage from the city flow into the intersecting sewers, to be finally emptied into the drainage canal. As a matter of fact, some localities drain into the lake. At one fashionable hotel on the lake, where the bathing facilities are extensively advertised, a hotel that has become a resort of southerners during the summer, the sewage enters one street and the beach is just around the corner. In that hotel there are usually victims of typhoid; Dr. Lewis was one of them last January. Although the water is not supposed to be used for drinking purposes, it is used in the kitchen and for bathing, and it is easily understood how infection may occur. In Chicago, and it is an important factor to be recommended in every community, publicity is advocated regarding the actual condition of the water. When the intake is contaminated, as occurs at different times, the fact is announced in the newspapers, and the people are advised to boil the water. Of course, boiling the water is not all sufficient, but publicity is a step in the right direction, for it notifies the public regarding the actual condition of the water supply.

Dr. E. A. Pierce, Salem, Ore., said that two years ago in one of the meetings of the State Board of Health it was decided to look over the water supply of the different institutions of the state. Dr. Pierce's residence being in the Willamette Valley, he made an effort to inspect the water supply on that region. In Salem there was a mild epidemic of typhoid which started in Stayton, about 12 miles north of Salem. The sewage from one or two infected families was drained into a small creek which runs through Salem. The contaminated water infected several people living at Turner, a few miles below. Later the reform school was in turn infected, though the pupils were forbidden to use the water for drinking; some of them did so and a number of cases appeared. In the penitentiary, where the water was used for bathing and for toilet purposes, there were a number of cases, and in the insane asylum, which also used the water, a number of patients were infected. A large number of samples of water were collected, and it was found that they were infected, and also that a large number of surface wells near the creek were contaminated. Despite all efforts along the creek and in the suburbs, the health officials were seriously handicapped on account of lack of an adequate sewerage system. After a time Mill Creek purified itself, and, after a few deaths, and a large number of mild cases, the condition of affairs was greatly improved. The city supply of water was overhauled. This is taken from the Willamette River, after passing through a large gravel screen, and, at the present time, it is apparently free from contamination. Of course, the use of Mill Creek water in the institutions has been abandoned, and the city is now as healthy as any. In the treatment of sewage in the suburban districts and in the outlying portion of the city, where there were no sewers, the septic tank system was adopted, as far as possible, and that method has been a great help. At the asylum farm, 6 miles northeast of the city, there is one septic tank which is accommodating the night soil of sixty patients. It has been inspected regularly since it was built two years ago, and is working splendidly. A large amount of waste is passing through it, and at the last examination the sludge at the bottom of the tank was scarcely perceptible, although it has never been removed. The scum on top of the fluid is six or eight inches deep, and the effluent is clear and not objectionable, the effluent passing into an open ditch. Dr. Pierce has one of these tanks at his home and it is working well. There is a large tank at the Chemawa Indian Training School, which is giving excellent satisfaction. Formerly the sewage of the institution of about 600 pupils and teachers was conveyed through open ditches a long way off across the field toward the river, and there was much annoyance and complaint regarding the bad odor arising therefrom. With the adoption of the septic tank, the condition has been entirely relieved, the effluent passing along the same ditch. The health officials instituted an investigation of the different institutions and towns along the Willamette River and streams tributary. These are more or less contaminated with sewage all the time. Oregon City established a filter, the water being taken from the river. The bacteriologic count of the water after having been treated by the filter, as compared with Bull Run water at Portland, is almost equal to it. It is hoped later to have the same plan adopted in other cities in the state. Mill Creek at Salem has apparently purified itself, but it is only a question of time, of course, when it may become contaminated again. Dr. Pierce declared that inland water ways should be protected against contamination by sewage, and the streams should be allowed to return to their virgin purity. He believes that the septic tank should be adopted for the treatment of sewage wherever the sewer can not be used, and in all suburban localities. Even in the large towns and cities he thinks that the same plan can be employed. The sewage farming plan as practiced largely in Europe has given excellent results. In reply to a question he described the tank at the asylum farm. It is ten feet long, five feet wide and four feet deep (the depth below the level of the fluid). The sewage enters at a slight grade from the toilet, and there is a pipe with an elbow that carries it about eighteen inches below the surface of the tank. This prevents any disturbance of the surface. The outlet is at the other end of the tank, on an exact level with the inlet, and is submerged to the same depth. The tank is built of cement, and is covered with a cement or iron cover. Most of the tanks have been sealed as described, but the one at Chemawa is not sealed, but has a shingle roof over the entire tank and a large air space above it. This tank treats the sewage of 600 people, nature has sealed the surface with a scum which is tough and leathery, and so the air is entirely excluded. Dr. Pierce does not believe that it is necessary to seal the tank, as nature makes that provision. The anaërobic bacteria thrive in the absence of light and air, hence the first thing nature does is to seal the tank. All, then, that is necessary is to protect it with a cover to prevent débris from falling into it. The tank at Chemawa is fifty feet long, fourteen and one-half feet wide, and four and one-half feet deep. There are two baffle boards, one about ten feet from either end and a wire in the center. A mistake was made in its construction, as it was not originally made for a septic tank, but was intended simply for a storage tank. The weir was too high and enough space was not left for the free passage of sewage over the weir. That, however, has been remedied. Mr. A. G. Strang, engineer at the State Insane Asylum, who has had experience in this line, says that he does not favor the weir or baffle boards. Dr. Pierce's object in advising the weir and baffle boards, particularly in large tanks, is to break the currents, and in all the tanks that he has been consulted about, he has had them put in and they have given perfect satisfaction. A tank to work properly should have sufficient water supply to fill and empty once in twenty-four hours, and should have a capacity of about thirty gallons to each person using it. There should not be any odor from the tank, for the reason that nature seals the tank, and the effluent should not be offensive. Dr. Pierce believes that the action of the aërobic bacteria on the effluent as it emerges into the air and sunlight completes the work that was begun in the closed chamber by the anaërobic bacteria. A sand or gravel filter could be attached with admirable results.

Dr. H. G. Beyer, Washington, D. C., said that he has always been surprised at the slowness with which the septic tank system has grown into prominence. Prevention of disease begins with the soil. Filtering and boiling the water after first allowing it to become contaminated through contact with polluted soil seems to him like putting the cart before the horse. If the soil were not polluted this filtration might be unnecessary. Human excretions are the most serious causes of soil pollution. If the soil were kept from this pollution by a good system of septic tanks, or by a proper sewage system a great deal of disinfection, Dr. Beyer thinks, would be unnecessary. He does not think that it would be extravagant for every block in town to have a space set apart for a septic tank. In this way every house in a city might be sure of sending its sewage into this filter; it would then not make any difference whether or not a sewer leaked or whether the sewage flows through a regular sewer or is taken care of by the ground, the soil itself remains unpolluted. It seems to Dr. Beyer that this is a very much more effectual method of sewage disposal than any other he can think of, and it is for reasons such as these that the slowness of the growth of the septic tank idea in the prevention of the spread of infectious diseases, is to be deplored. Of course, at first health officials would have to proceed very carefully in doing away with the filtration or purification of water, and that the latter procedure should be incidental to the imperfect disposal of sewage. The west coast is fortunate in its water supply, but unfortunate in its sewage disposal. The soil in large sections is a loose surface soil with a subsoil of hard pan, which is really lava and is absolutely impermeable to water. Any drainage will follow the subsoil for miles, so that water may be taken at one point containing infection coming from a great distance.

MATERNAL SYPHILIS.*

GEO. S. WHITESIDE, M.D.
PORTLAND, ORE.

Hereditary syphilis may be a transmission of disease from the father alone or from the mother alone or from both together. Maternal syphilis may be defined as only the disease of the pregnant woman, but to-day we may also consider, briefly, its influence on her offspring as well.

Syphilis in the mother, without paternal disease, is rare; the reverse is common. The large majority of married women afflicted become so from their husbands. Bulkley records 85 cases out of 120, or almost 75 per cent. Obstetricians and gynecologists are daily called to examine pregnant women and often are the first to have a chance to observe syphilitic disease in the innocent young wife pregnant for the first time, and yet but brief mention is made of it in text-books and treatises on obstetrics and gynecology. The former are more than half devoted to operative obstetrics, and the latter almost wholly to operative gynecology. For almost half a century Ricord, Colles, Diday, Fournier, Hutchinson, Bulkley and others have presented evidence enough to convince the most skeptical that syphilis is a common disease and a serious menace to the happiness of marriage and of motherhood; yet the text-books, one copied largely from the last preceding, hardly even mention its existence.

---

* Read in the Section on Obstetrics and Diseases of Women of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

The diagnosis of syphilis in married women, especially those in the higher classes of society, is surrounded by difficulties. As a rule, the woman herself is ignorant of the nature of her trouble and unobservant of trifling and transient symptoms. Her conscience does not accuse her of illicit intercourse and she is not on the lookout for evidence of disease conveyed through her marital relations with the man of her choice. She believes him to be as pure and above reproach as she herself is, and suspicion of the existence of disease in him is slow to enter her mind. It is well that this should be so, for obvious reasons, but serious obstacles confront the physician when the ignorant or unprincipled husband infects his innocent wife.

Remember at all times Hutchinson's advice "not to be overconfident in the diagnosis of syphilis," because when all the typical symptoms are present the diagnosis is plain and easy, but there are cases in which it is difficult or even impossible. It has been said that syphilis is a mimic, that at times it simulates almost every form of skin disease or mucous membrane affection or even may be confounded with tuberculosis or cancer. On the other hand, a disease at once so common and so far-reaching in its effects should not be long out of one's mind when studying gynecologic cases, and this is doubly important when it concerns the welfare not only of the woman herself, but also of the unborn child and its relative place in society, as well as the future of the family.

When the pregnant woman presents a typical chancre, exanthem and other symptoms, the diagnosis is easy and the course clear, but how often is a physician called to attend a miscarriage case in which the fetus has died in utero from some syphilitic accident or in which syphilitic disease of the placenta has caused the birth of a child too immature to live. Yet do not make the mistake of supposing that every macerated fetus has been the victim of luetic visceral disease or that every puny, premature infant is the victim of syphilitic mischief. Physicians know how common these accidents are when no syphilis exists and what a variety of causes may occasion the one or the other. Jonathan Hutchinson[1] warns us that intrauterine syphilis is the exception. In fact, he declares that he has never seen an infant surely syphilitic at birth. On the other hand, it is evidently impossible for an infant whose mother is syphilitic to escape infection in utero unless her disease has been so very recent that no time is given for its development before parturition.

Often the first notice the attending obstetrician has of the existence of maternal syphilis is in the development of the taint in the infant a few days or weeks after birth. Such cases are very distressing and often troublesome to the physician. There have generally been slight symptoms which should have been as danger flags, but which were so mild that they were overlooked or else have been explained away as the result of some other affection. Sometimes an ache or a pain is supposed to be neuralgia or rheumatism, sometimes a superficial skin trouble is not rightly diagnosticated. I have seen a case in which a well-known gynecologist opened the abdomen in search of extrauterine pregnancy only to find a normal intrauterine pregnancy and later to have it proved that the hemorrhage from the uterus, which had been the symptom leading him to operate, had been the result of syphilitic placental disease. I have seen more than one case of what were thought to be varicose ulcers of the legs in pregnant women heal rapidly and completely under iodid of potash, in spite of the fact that the venous return was still obstructed by the uterine tumor.

Do not mistake me. I do not mean to emphasize the specific taint as the most important etiologic factor in most puzzling cases, but I wish to urge physicians not to forget the possibility of it. I am aware that psoriasis, eczema and some other forms of skin disease are apparently aggravated by an intercurrent pregnancy, but that should not blind us to the possibility of a recently acquired syphilis. In genitourinary practice I have had abundant opportunity to notice the fact that many husbands are inconstant during the later months of their wives' pregnancies. It is human nature. However much we may deplore it and despise the man for it, let us remember the fact. Many a woman has become infected because of disease acquired by her husband when she was not physically able to satisfy his demands. Having committed adultery, acquired syphilis, infected his wife and, through her, condemned his offspring yet unborn, the husband is slow to acknowledge his unmanly conduct. As a rule, he rather hides the fact from his wife's physician, thereby often causing delay in the administration of treatment because of an incomplete or obscure diagnosis. On the other hand, if the husband does not pursue this course he goes to the other extreme, driven by remorse for what he sees he has done he tries to remedy the evil by a full confession to the physician. In such an event, the obstetrician's way is clear and his duty plainly not to wait for symptoms in the woman, but at once to begin treatment either by inunction or by the administration of gray powder as a prophylactic against the transmission of the disease to the fetus.

Should the fetus have inherited the disease from the mother, either as the result of so-called germ infection or from an intercurrent acquired syphilis beginning during gestation, but after conception, then what will be the prognosis for the child? Without treatment, the mother may miscarry or may bring the fetus to term. The latter is not at all uncommon. In that event, as a rule, the child seems sound and well at birth, but signs of inherited taint show at the end of two or three weeks. If the child survives the first acute, febrile outbreak of secondary symptoms, it will probably respond to treatment and very likely grow up an apparently well individual. Among the better class of patients this is generally the case. When the system is less able to withstand an acute febrile disease, as among the poor in large cities, the mortality is, luckily, much higher. Even in cases in which some deformity of bone has taken place, as, for example, in hydrocephalus, antisyphilitic treatment often causes an absorption of the products of the disease and an arrest of pathologic growth, and in time the deformity is no longer noticeable.

---

[1] Syphilis, edition 1901, p. 78.

Mercury is best administered to the infant by inunction, but it may be necessary to use the gray powder, in spite of its action on the bowels, which, if need be, may be controled by opium. Mercurial medication should be continued at least as long as there are symptoms or signs of disease, and many authorities advise it for at least a year. I believe it is best to compromise by keeping up treatment for two months after all signs have vanished. I have no doubt Hutchinson is right in thinking that mercury given in early infancy has a detrimental effect on the permanent teeth later. This can not be absolutely proved, however.

To sum up this brief paper, I would say:

1. Look oftener for syphilis, as the presence of this disease will frequently explain obscure symptoms.
2. In the pregnant syphilitic woman give mercury promptly and fearlessly. Only in this way can the health of the fetus be protected from the inherited taint.
3. Give the syphilitic infant every care and mercury. The child should recover entirely in a few months.

After thorough treatment the late forms of hereditary syphilis are rare. I will not discuss the principles which should guide us in putting syphilitic children to the breast. These have been fully and ably discussed by Fournier and others; besides, in these days of bottle-fed babies, the subject is not so important as it once was.

PULMONARY TUBERCULOSIS AS AN OBSTETRICAL COMPLICATION.*

CHARLES SUMNER BACON, M.D.
CHICAGO.

Probably from 1 to 1.5 per cent. of all pregnant women have tuberculosis in such degree that it can be detected if careful examination is made. Freund found about 12 cases in 1,000. Of these patients, nearly half were in a serious condition. The fact that only about 50 per cent. of the cases discovered were comparatively mild suggests the possibility that a larger number of mild cases could have been discovered if a stricter examination had been made. We have not a sufficiently large statistic from other clinics to justify the statement above made concerning the frequency of the disease, but it is probably true because the ratio given corresponds to the frequency ratio of tuberculosis among adults between 15 and 45 years. This ratio is obtained from the consumption mortality rate and the duration of the disease. According to the United States census of 1900, there are 252 deaths annually from tuberculosis in 100,000 adults between 15 and 45 years of age. In order to find the number of cases of tuberculosis in 1,000 adults, we should have to know the duration of the disease, and there are few data bearing on this point.

Hoffman repeats the common statement that patients live two years after the disease can be diagnosed. In the Phipps report the records given would indicate a duration of at least five years. From estimates given me by clinicians of experience, it would seem that an assumption of the average duration of the disease of five years might not be far from the truth. With this coefficient and with a mortality of 2.5 per mille, we would have a frequency of 12.5 per mille, or, in other words, about 1 in every 80 adults between 15 and 45 years of age has consumption. This refers, of course, to what we may call clinical tuberculosis and not to the pathologic condition of the individual. As is well known, according to the examination of certain pathologists, some tuberculosis is found in the great majority of postmortem examinations, showing that some time in his life nearly every individual has a little tuberculosis.

If, clinically, from 1 to 1.5 per cent. of all adults have tuberculosis, the proportion is about the same as in pregnant women. There is, indeed, very little reason why the ratio should be less in pregnancy, for it is rare that tuberculosis is a cause of sterility. The only conditions in which tuberculosis might be a factor in causing sterility are the tubercular involvement of the genital organs by a descending tuberculosis and the atrophy of the egg because of anemia, which either results in failure of ovulation or renders it incapable of fertilization. Both of these conditions are probably so rare that they are nearly negligible.

Using the ratio of 1 to 1.5 per cent., we should find that among the 60,000 women confined in Chicago each year from 600 to 900 are tubercular. In the whole United States, we should have, approximately, 40 times as many, or from 24,000 to 36,000. Although perhaps only three-fourths of these cases are of the advanced type, it is evident that the frequency of the condition makes it of great importance medically, socially and economically.

There has been much difference of opinion concerning the effect of pregnancy on the progress of the disease. Formerly the idea was prevalent that pregnancy improved the tubercular condition and even that it sometimes caused a cure. No doubt this idea was based on clinical observation and cases of improvement are occasionally observed to-day. Such an improvement may be attributed to a stimulant to general nutrition, an occurrence frequently seen, and to better general hygiene, including more rest, etc. That chemical changes in the blood caused by fetal products might be inimical to bacterial growths is not impossible.

In many cases, however, there is no doubt that pregnancy has a bad effect on the tubercular process. There may be a rapid development of tuberculosis in the lungs or an acute miliary fever may appear. The bad effect is much more apt to appear when the disease has already progressed so far or when nutrition is low from other causes. For this reason nausea and vomiting or other gravidal toxemias may increase the danger.

In the latter part of pregnancy disturbances arising from pressure against the diaphragm by the growing uterus may interfere seriously with an already impaired respiratory function.

Labor is very apt to be an unfavorable factor in the development of the disease. In all severe forms the exhaustion from the loss of energy and from the depletion of the system is extreme and not rarely leads to an immediate fatal termination. The detrimental influence of the latter part of pregnancy and of labor is revealed during the puerperium, which is characterized by a rapid progress of the disease. The puerperium itself, with its usually enforced confinement in imperfectly ventilated and overheated rooms, is injurious and its influence is added to that of labor. As a result, this period is always a critical one, even for milder cases and for those more advanced it is very dangerous.

---

* Read in the Section on Obstetrics and Diseases of Women of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

The effect of tuberculosis on pregnancy is slight except in severe cases, when there is considerable fever and coughing. In those cases abortion is common. Placental or decidual hemorrhage, with injury to the egg, is much less common than in case of cardiopathies or nephropathies. Even when there is considerable emaciation and general nutritional disturbance it is somewhat astonishing how little the fetus suffers. There is less tendency to abortion than in complications of pregnancy with heart or kidney diseases.

The fetus may be infected, but this occurs only rarely. Probably such infection takes place when there is a solution of continuity in the placental partitions between maternal and fetal blood. As such a break in the walls is less common than in many other infectious diseases, like smallpox, scarlet fever, cholera, etc., so fetal tubercular infection is less common than fetal smallpox, fetal scarlet fever and fetal cholera. The chances are that the child will be born free from tuberculosis if abortion does not occur. It is likely that it may possess a predisposition to the disease, but the pathologic condition is not conclusively demonstrated.

In mild forms of the disease, labor may be quite normal. In emaciated patients both the uterine and the abdominal contractions may be feeble and inefficient. This failure in the forces of labor, combined with the weakness of the patient, is an indication for an early interference.

Generally it is the puerperium which shows most markedly the effect of consumption. When the exhaustion of labor is considerable the patient is apt to die in the first two or three succeeding days; in milder cases she is quite apt to go to pieces. Even those who hold that pregnancy generally benefits a mild type of the disease admit that the puerperium almost always unfavorably influences it.

The French are fond of concisely summing up the treatment of tuberculosis complicating pregnancy by applying the formula of Peter concerning cardiopathies to these cases, *Fille pas de mariage, femme pas de grossesse, mere pas d'allaitement.* So far as the rule applies to the unmarried, it can be endorsed without question. If a tuberculous process undoubtedly exists there can be no excuse for a marriage that can only result in dangerous complications. The only difficulty arises when we have to decide for those apparently cured. Here each case must be decided for itself. The sexual life is a source of danger independent of the fear of pregnancy.

In this connection, the question of imposing restriction on the marriage of tuberculous individuals by legislative enactment might be discussed. As is known, such propositions have been made in some states. To one who is in touch with the spirit of our people, it seems very doubtful if such a law could be carried out. The machinery for its execution would be too repulsive to the prevailing sentiment. I believe that much more can be accomplished by educating the people concerning the infectiousness of the disease and the ravages caused by it.

When we come to consider the case of the married woman we may have to make a slight exception to the French rule. Suppose we are consulted by a man and wife in comfortable circumstances. They desire greatly a child. The wife has some tuberculous involvement of the lungs which is not extensive but which will not entirely yield to any treatment that has heretofore been instituted. She can be put and kept in the best hygienic surroundings during her pregnancy and puerperium. The child can be cared for in a proper manner. If such a woman, fully informed concerning the risks she runs, refuses to be dissuaded, I think the physician may rightfully consent to care for her in her attempt to secure the much-desired pregnancy.

This is a rare case, however, and interferes but little with the rule that prohibits pregnancy in a tuberculous wife. Certainly in all cases in which the circumstances do not allow such an ideal management of the pregnancy and the puerperium, and when the woman must care for her house and remain a large part of the day indoors or removed from pure air, when she can not have sufficient nourishing and well-cooked food and when she would be obliged to nurse and care for her baby, conception should be absolutely forbidden.

For these patients, artificial sterilization may be a legitimate operation. Its permanent consequences should be thoroughly explained to both husband and wife in order that later recovery of the wife should not lead to censure of the physician for a mutilating operation. The probability of a recovery should be carefully weighed before making a decision. When some operation is determined on that one which does not remove the ovaries should be chosen. The vaginal resection of the tubes is generally the simplest and best, unless some other pathologic condition indicates a laparotomy, when, of course, the abdominal resection would be done. Pincus and others recommend his method of atmocausis, or obliterating the uterine cavity by burning it out with superheated steam. With proper apparatus and with experience in the operation, this method would seem a good one, but it has not gained adherents in this country.

When a probability of a cure of the consumption remains, so that a subsequent pregnancy would be allowable, or when for other reasons a sterilizing operation is impossible, some means of preventing conception may be advised. No physician of experience would feel justified to rely on giving the advice to abstain from sexual intercourse. The preventive measure should be advised only as a measure of last resort and not as preferable to a sterilizing operation. For many reasons it is less desirable and less scientific.

When we come to consider the case of the tuberculous pregnant woman we must decide whether or not the pregnancy should be interrupted. The decision will depend largely on the circumstances of the patient. If she is able to afford the best of care during pregnancy and puerperium and also to care for the child, she should be encouraged to continue the pregnancy, especially if the tuberculous process is not very advanced. When, on the other hand, she can not hope for hygienic surroundings and good food, nor for help in the care of the child, she may be advised to have an abortion performed. A complication of tuberculosis with heart or kidney disease, with hyperemesis or with other serious acute or chronic disease furnishes additional indication for inducing abortion. The operation should be decided on before the twentieth week. Later, an attempt should be made to carry the child to the period of viability.

Rapid emptying of the uterus is the best method of inducing abortion. Anesthesia properly administered is not contraindicated. I believe that ether is the safe anesthetic here, as in other cases.

If pregnancy be allowed to continue, the patient should be treated according to the principles now accepted as the best adapted to control or to cure the disease. According to these principles, the essential rules of treatment direct: 1. She should live in the open air as much as possible, *that is, she should breathe fresh,* pure air. 2. She should be well fed with good, nutritious food. 3. She should avoid exhaustion or fatigue. Whether in carrying out these rules she should remain at home or go to a sanitarium depends on individual circumstances. I do not see that the details of management differ from those in any other case of consumption. Symptomatic medicines like those for coughs, night sweats, etc., are to be administered as necessary.

After the period of viability is reached, the question of inducing labor will come up for decision. Rapid or gradual failure of nutrition, due to loss of appetite or to stomach disturbances or to exhausting discharges, will be an *important indication for the operation.* Hemoptysis would be an urgent indication. Exhausting, uncontrollable cough or laryngeal or pleural complications or other severe respiratory disturbances, like dyspnea, may call for artificial delivery at the earliest possible moment. *As in all other cases of induction of* labor, the operation should be postponed till the thirty-sixth week unless the urgency of the symptoms calls for earlier interference. The method of operation should be that which furnishes quick relief from the urgent symptom and which also assists and hastens labor. For these reasons the bougie method should not be employed. The cervix may be dilated if necessary with instruments or with the *finger, the membranes ruptured and then,* after the escape of the liquor amnii to relieve the symptoms due to pressure on the diaphragm a metreurynteur is introduced through the cervix into the amniotic cavity. In the most urgent cases, a vaginal Cesarean section may give better chance of saving both mother and child. With this operation, as well as with any operation during labor for which anesthesia must be employed, oxygen should always be provided for eventual need.

The proper management of labor in a consumptive involves a careful watching of the patient and efficient, timely interference on the first appearance of evidences of exhaustion. Oxygen should be *used freely and strychnin* as a tonic should be given hypodermically as indicated. Post-partum hemorrhage is not particularly common in such patients, but its possibility should be anticipated. and provision made for instant control. Subcutaneous injections of physiologic salt solution may be necessary and the solution must be prepared beforehand.

The well-known *fact to which I have already referred,* that the puerperium is the period of greatest danger to the mother, should prove that it ought to receive the most careful and rational management. For the first forty-eight hours the most imminent danger is from circulatory disturbances. Oxygen, strychnin and physiologic salt solution, with most careful watching, are our weapons to combat this danger. Later, we must look after *nutrition and fresh air. The common fear of cold* air, which leads to the imprisonment of the patient in an overheated, unventilated room, is often chiefly responsible for the rapid emaciation. There is no reason why she should not be carried to an outdoor bed or couch, where she can lie most of the day unless the weather is very bad. This plan may be begun as soon after labor as the immediate danger is passed. If the patient lives in a large city in an apartment she may still find some benefit from a porch. If the air is very smoky and harmful she should be removed to a proper sanitarium or to better surroundings if possible within a week of her confinement.

Under no circumstances should she nurse the child, and it should not be kept in the same room. When possible it should be fed by a wet nurse. There is no danger to the wet nurse from the child, for it is almost never tuberculous; of course, arrangements for the feeding and care of the child should be made before it is born.

It may be difficult to make a differential diagnosis between *tuberculosis in the puerperium* and genital wound infection. The absence of the local symptoms of the latter with the history of the fever should enable us, generally, to separate the two diseases. Complication of puerperal fever with tuberculosis of the puerperium is, of course, of greatest danger.

We all know that there has been considerable advance in the method of control and treatment of tuberculosis in the last few years. A large ray of hope has partly dissipated the depressing gloom of the despair of the past. This improved outlook for the future is due to the advance of our knowledge of the disease and to the demonstration that it can be cured by hygienic management. I have tried to call attention to the importance of applying these more rational methods of cure of consumption to the disease when complicated with pregnancy, labor, and the puerperium. I believe that by a careful but thorough use of the fresh air, rest and feeding cure, many more of the 30,000 consumptive pregnant women in the United States can be brought safely through pregnancy and the puerperium and eventually, perhaps, be cured. This management before and after labor and a free use of oxygen in labor and in the subsequent disturbances are the points to which I desire to call especial attention.

DISCUSSION.

Dr. Mariana M. Bertola, San Francisco, mentioned one case of transmission of tuberculosis to the fetus. The mother was unquestionably tubercular. She was put on treatment similar to that advocated by Dr. Bacon, and carried the child to term. The child was emaciated, undersized and presented symptoms of tuberculosis. It was removed from the mother, fed artificially and kept out of doors as much as possible. After two months it died, and at the autopsy tuberculosis of all its organs was found. Although the mother still has bacilli in the sputum, her general condition is better than before. She has not had any more children.

Dr. J. F. Taussig, St. Louis, said that this condition occurs often and the general practitioner should know more about it. As a result of two cases in his practice he made inquiries, and was surprised to find how *few general practitioners realized* that there is justification for the induction of abortion or premature labor on account of tuberculosis. The question has not been discussed sufficiently. *Every case should be judged* by itself. In arriving at a decision the physician should be governed by three things. First, the site and stage of the tuberculous process. *If in the larynx, the case is practically* hopeless, and everything should be done to save the child. In such a case the physician should not interfere, because the mother's life is *practically* lost, but that of the child may be saved. A similar condition exists in a case of advanced pulmonary tuberculosis. In less advanced cases the physician should be *governed largely by the weight of the mother.* If she is not gaining in weight, he is justified in interfering; otherwise not. All such patients should be kept constantly under observation. *Second, the state of pregnancy.* Physicians would be more inclined to interfere in the first half of pregnancy than in the last half when they must consider the probinfluence is added to that of labor. As a result, this period is always a critical one, even for milder cases and for those more advanced it is very dangerous.

The effect of tuberculosis on pregnancy is slight except in severe cases, when there is considerable fever and coughing. In those cases abortion is common. Placental or decidual hemorrhage, with injury to the egg, is much less common than in case of cardiopathies or nephropathies. Even when there is considerable emaciation and general nutritional disturbance it is somewhat astonishing how little the fetus suffers. There is less tendency to abortion than in complications of pregnancy with heart or kidney diseases.

Although the mother still has bacilli in the sputum, her general condition is better than before. She has not had any more children.

Dr. J. F. Taussig, St. Louis, said that this condition occurs often and the general practitioner should know more about it. As a result of two cases in his practice he made inquiries, and was surprised to find how few general practitioners realized that there is justification for the induction of abortion or premature labor on account of tuberculosis. The question has not been discussed sufficiently. Every case should be judged by itself. In arriving at a decision the physician should be governed by three things. First, the site and stage of the tuberculous process. If in the larynx, the case is practically hopeless, and *everything* should be done to save the child. In such a case the physician should not interfere, because the mother's life is practically lost, but that of the child may be saved. A similar condition exists in a case of advanced pulmonary tuberculosis. In less advanced cases the physician should be governed largely by the weight of the mother. If she is not gaining in weight, he is justified in interfering; otherwise not. All such patients should be kept constantly under observation. Second, the state of pregnancy. Physicians would be more inclined to interfere in the first half of pregnancy than in the last half when they must consider the probability of saving both the life of the mother and the child. Third, the social condition of the patient. As Dr. Bacon mentioned, hygienic treatment is of the utmost importance. Hence, the physician would be more inclined to interfere in the case of a woman belonging to the working class than in the case of a woman of a higher or better social plane with whom correct hygiene can be carried out. It is to be hoped that in the future, when sanatoria are more numerous, physicians may be able to do more for the poorer class, and thus be able to save the lives of these women, which is now impossible in many cases.

Dr. Effa V. Davis, Chicago, said that physicians are too ready to say to a pregnant woman that they will relieve her of her burden if she is not well. In fact, the laity has come to expect that of physicians. Dr. Davis does not see any reason for performing an abortion just because a woman lives in bad surroundings and is unable to care for herself. The life of the unborn child should not be destroyed, except for some very good reason. If it is only to curtail the misery of some poor woman of the slums, it is poor practice. It is far better to save the life of the child than to prolong the life of the unfortunate mother. The position of Penard of never producing an abortion is a much safer one than the one where physicians are expected by the laity to do it on any pretext. Dr. Davis has found that many women have syphilis, acquired not through their husbands, but through their fathers. That kind of syphilis is likely to baffle the physician. A child came under Dr. Davis' care born of a mother who was syphilitic through her father. She had given birth to many syphilitic children, none of which lived. The husband of this woman was perfectly well. Dr. Davis treated the woman all through her pregnancy, and she gave birth to what seemed to be a healthy child. The child was treated with bichlorid baths after the appearance of a rash when five weeks old and apparently recovered. After seven years the child had a syphilitic iritis. Physicians ought to be very careful about saying that they have cured patients with two or three months' treatment.

Dr. W. O. Henry, Omaha, protested emphatically against producing abortion because the mother is tuberculous. The physician's business is to save life, not to take it. Of course, it is unfortunate when a tuberculous woman becomes pregnant, but the physician has no right to do a criminal act because of that. He should use all possible means to help the mother during her pregnancy and puerperium, and should endeavor to save both the mother and the child, but he should never take the life of the child.

Dr. J. H. Carstens, Detroit, agreed with Dr. Bacon, but said he believes physicians can do more by education. People know that consumption is a dangerous disease, and that it is infectious, and they do not marry a consumptive if they know it. Young men and young women consider this. He does not agree with Dr. Bacon that physicians are justified in sterilizing a woman because she has consumption. That is absolutely wrong. It is never justifiable under any circumstances. As far as producing abortion is concerned, Dr. Carstens thinks that Dr. Davis hit the nail on the head, but he would not say that physicians should never do it because there are exceptional, rare cases. Those women stand confinement pretty well. Dr. Carstens has been asked to operate for fibroids, lacerated cervix, etc., for the purpose of relieving some condition of the system which he has cured with mercury or iodid of potash without operation. Syphilis is more common than any other disease except hysteria. It produces almost every symptom, in season and out of season. In obscure cases, the physician should think of syphilis by giving iodid of potash, and he is quite likely to cure the patient.

Dr. F. D. Donoghue, Boston, said that aside from the moral aspect, the induction of abortion is a confession that the physician can not cure the disease, and is a temporary makeshift, at best. The patients in whom Dr. Bacon would produce abortion are almost sure to die. In the incipient case, the patient is almost sure to recover under good treatment. A woman with emaciation, great loss of flesh, high temperature, pregnant or non-pregnant, is sure to die. Why sacrifice a useful life by producing abortion? The function of the physician is to advise against pregnancy in these cases, and if the advice is not followed, the parties responsible for increasing the danger are to blame, not the adviser. The time has gone by when it can generally be said that the profession will protect patients from the effects of their own acts.

Dr. C. S. Bacon said that it is difficult to determine in a given case whether a child is born with tuberculosis. Dr. Bertola's case is very interesting, and it would be well if we knew that the patient was not exposed to tuberculosis after birth. If the child was exposed, it is not unreasonable to assume that the child contracted the disease in that way. The case as related does not prove the transmission of tuberculosis. He said that Dr. Taussig's indications for the induction of labor and abortion are exactly in line with his own views. Dr. Bacon said that a careful reading of his paper will show that in regard to the right to induce abortion in all cases of tuberculosis complicating pregnancy he agrees entirely with those who oppose it. He has no doubt that the suspicion of the presence of tuberculosis is often improperly made a reason for inducing abortion, and so far as the general objection goes, he agrees with Dr. Carstens and others; but when the matter is considered from the practical standpoint, the question is a different one. Dr. Donoghue seems to believe that tuberculosis is not so very dangerous, in the incipient stages at least. It has been demonstrated that even in the incipient stages the disease progresses rapidly, and the woman may be in a very dangerous condition or may die during the puerperium. The woman with a rather serious complication is not necessarily condemned to death because she becomes pregnant, if the pregnancy is removed at once. Certain indications for the induction of abortion are recognized, although the Catholic Church prohibits abortion under any circumstances, and there is something to be said for that side; but if any reason for the induction of abortion is recognized, or if it is ever justifiable to destroy the child in utero, physicians must recognize that there is an indication in those cases. Of what use is it to let a woman who has rather advanced tuberculosis go on and probably die during labor or in the puerperium? What will become of the child? The mother of a family is an extremely important member of society. Why should physicians say that they have absolutely no right to try and save her life, when otherwise she will bring into the world a child that will have no care after it is born, and therefore probably will die? Dr. Bacon said that he can not agree to the objections made by those who, perhaps, see too little of these cases, and whose objections are theoretical and not practical. Dr. Carstens objects to the induction of abortion and also objects to sterilization. His advice, if carried out, will favor the increase of tuberculosis by increasing the number of children born to tuberculous parents. Dr. Bacon knows of no objection, moral or otherwise, to sterilization. In the paper he emphasized that all the circumstances should be considered and that the patient should be informed of the situation so that she takes the risk and not the physician.

Dr. G. S. Whiteside said that he does not quite understand what Dr. Davis meant by syphilis through the father. He doubts if she meant inherited syphilis, because there probably is no authentic case on record of syphilis having been transmitted to the third generation. Dr. Whiteside did not mean to imply that infants should be treated for only a few months. On the other hand, it has been demonstrated time and again that no matter how long antisyphilitic treatment is kept up in an infant, it does not bar the later developments of syphilis, such as syphilitic iritis or keratitis, bone lesions, syphilitic disease of the nervous system, etc. Although these late manifestations are more common in patients treated for only a short time, they are not unknown in those treated for a long period of time.

Medical Advertising.—Classify advertised remedies under four heads: Reputable, doubtful, semi-fake and fake. LACTIC ACID IN GONORRHEA.

SWITHIN CHANDLER, M.D.
Surgeon to Garretson Hospital. Gynecologist to Charity Hospital.
PHILADELPHIA.

One must realize that one of the many unpleasant sequences so often following a gonorrhea in the female is a cervical infection, accompanied by an irritating and disagreeable discharge.

Again, when it has been estimated that 50 per cent. of all pelvic disorders in the female are due to gonorrheal infection, and that in the great majority of these infections the cervix is affected, it impresses on us the necessity of combating this disease.

It is comparatively easy to eradicate the disease from the urethra, yet at times it is difficult without local attention strictly applied, but it is a very different affair when the cervix is diseased. The glands in the cervix are peculiar because of their deeper position and branched condition. They easily retain the cocci, which are ever a source of irritation and its resulting discharge. I have known in my practice such a discharge to have existed six years after a positive bacterial examination.

After many operations no credit is given for an operation most skillfully done for a most trying condition, because an irritating vaginal discharge from a diseased cervix continues after the patient is otherwise well and about, this discharge keeping the case fretting and nervous and baffling the ordinary douches to cure it. Neither the worry of the patient nor the inability to cure the case is a condition at which to wonder. It is annoying and distressing to a woman to have such a discharge, and it does keep her in an excited state. The inability to effect a cure is not to be marveled at because the ordinary douche nozzle is not the proper instrument to reach the glands of the cervix.

The physician paints the cervix with silver, and for a while all goes well, but sooner or later back comes the discharge, and he must go over his case again. At times he loses the care of the family, and another physician makes "history repeat itself."

These facts led me to investigate, and in a great majority of the cases of chronic vaginal discharge I was enabled to discover the gonococci, and to find that its habitat was in the cervical glands, in most instances being limited to them.

It then appeared to me that the only procedure was to destroy the glands, because to destroy the cocci without the destruction of the glands was highly improbable. Therefore, I injected drugs into the cervix. Silver and its preparation, pyroligneous acid, iodin, creosote, carbolic acid, lactic acid were tried, and now I am of the opinion that lactic acid is so far superior to any yet used.

Some agents cause too much of a slough, some only close the ducts, etc., but lactic acid, while causing a small slough, has never caused any ill result in any case yet, and has always responded to my expectations so far. In total, I have used it in 34 cases. Every case has shown the gonococci present before treatment.

The method is: First to cleanse the vagina and cervix thoroughly with warm water and cotton soaked in a water solution (4 ounces to 6 ounces) of pyroligneous acid. Expose the cervix by drawing it downward and into view by an ordinary long tenaculum. Then take an ordinary hypodermic syringe loaded with pure lactic acid, and inject just beneath the membrane a few drops of the acid. Continue this until the whole of the cervix is exposed as the superior and inferior lip is injected. It may be done in one sitting, or in a nervous case, if desired, in two or three sittings.

The accompanying table shows cases, both acute and chronic, which were so treated, and the results. Gonococci were found in every case.

I have since had an acute case in a patient aged 66 years, the oldest patient with acute gonorrhea I have ever treated.

The tabulated cases were treated at the Garretson Hospital, Charity Hospital, and in my private work. I wish to thank the resident physicians in the Garretson Hospital, Dr. Lopez in the Charity Hospital, and the other members of the staff of the hospitals for their courtesies in making bacterial examinations, in sending me cases, and in many other ways assisting me in the work.

†Each case was examined in 3 weeks and found cured; this column shows date of re-examination, at which time no further evidences of the disease were found.

Acute are so classed if not over 12 days. Chronic are so classed if over 40 days. Between these days or years are given only cases where gonococci were found and reported.

CONCLUSIONS.

The conclusions so far reached are as follows:

Lactic acid injection does cure cervical gonorrheal infection.

Lactic acid injection has no ill after effects.

Lactic acid injection stops the spreading to the endometrium of the body of the uterus in acute cases if treatment is started soon enough.

Ordinary douches and painting of cervix can give only temporary relief.

It is better to destroy the cervical glands, and this should be done as soon as diagnosis is positive.

An examination should be made, not only of the discharge, but if necessary (where that examination is negative) of the cervical membrane, with its glands.

Most of the chronic discharges are due to retained gonococci.

ability of saving both the life of the mother and the child. Third, the social condition of the patient. As Dr. Bacon mentioned, hygienic treatment is of the utmost importance. Hence, the physician would be more inclined to interfere in the case of a woman belonging to the working class than in the case of a woman of a higher or better social plane with whom correct hygiene can be carried out. It is to be hoped that in the future, when sanatoria are more numerous, physicians may be able to do more for the poorer class, and thus be able to save the lives of these women, which is now impossible in many cases.

Dr. Effa V. Davis, Chicago, said that physicians are too ready to say to a pregnant woman that they will relieve her of her burden if she is not well. In fact, the laity has come to expect that of physicians. Dr. Davis does not see any reason for performing an abortion just because a woman lives in bad surroundings and is unable to care for herself. The life of the unborn child should not be destroyed, except for some very good reason. If it is only to curtail the misery of some poor woman of the slums, it is poor practice. It is far better to save the life of the child than to prolong the life of the unfortunate mother. The position of Penard of never producing an abortion is a much safer one than the one where physicians are expected by the laity to do it on any pretext. Dr. Davis has found that many women have syphilis, acquired not through their husbands, but through their fathers. That kind of syphilis is likely to baffle the physician. A child came under Dr. Davis' care born of a mother who was syphilitic through her father. She had given birth to many syphilitic children, none of which lived. The husband of this woman was perfectly well. Dr. Davis treated the woman all through her pregnancy, and she gave birth to what seemed to be a healthy child. Lactic acid injection has no ill after effects.

Lactic acid injection stops the spreading to the endometrium of the body of the uterus in acute cases if treatment is started soon enough.

Ordinary douches and painting of cervix can give only temporary relief.

It is better to destroy the cervical glands, and this should be done as soon as diagnosis is positive.

An examination should be made, not only of the discharge, but if necessary (where that examination is negative) of the cervical membrane, with its glands.

Most of the chronic discharges are due to retained gonococci.

It is possible to cure this discharge by injection by this method into the cervical glands.

Cervical infection is always possible in gonorrhea in the female, but by prompt action, tubes, etc., may be spared future disease.

So far lactic acid used by this method is the best drug for injection.

A too deep injection of the lactic acid may cause a slough, which, while not dangerous, is to say the least annoying, and lessens the good result which should be obtained from said injection.

2010 Chestnut St.

A CASE OF CEPHALIC TETANUS, WITH PARALYSIS OF BOTH SEVENTH NERVES.

JAMES HENDRIE LLOYD, A.M., M.D.
Neurologist to the Philadelphia Hospital
PHILADELPHIA.

In 1870, Rose[1] described a rare form of tetanus in which the tetanic symptoms were sometimes (but not always) confined to the muscles of the jaw and throat and were associated with a paralysis of the seventh nerve. This paralysis of the seventh nerve may be said to be the most distinguishing symptom of this form of lockjaw, and the cases thus far reported have, without exception, arisen from wounds in the territory of the fifth nerve.

Although paralysis of the seventh nerve is the most characteristic symptom, this nerve is not the only one paralyzed in all cases, for in very few instances the motor nerves of the eye, the hypoglossal nerve, and the branches of the pneumogastric nerve supplying the muscles of the pharynx, have also been involved. Such an anomaly as these local palsies present in cases of lockjaw could not fail in time to attract attention, and the disease has been variously named cephalic tetanus, *kopftetanus*, and *tetanus hydrophobicus*, the last name having been used by Rose because of a fancied, but quite superficial, resemblance to rabies.

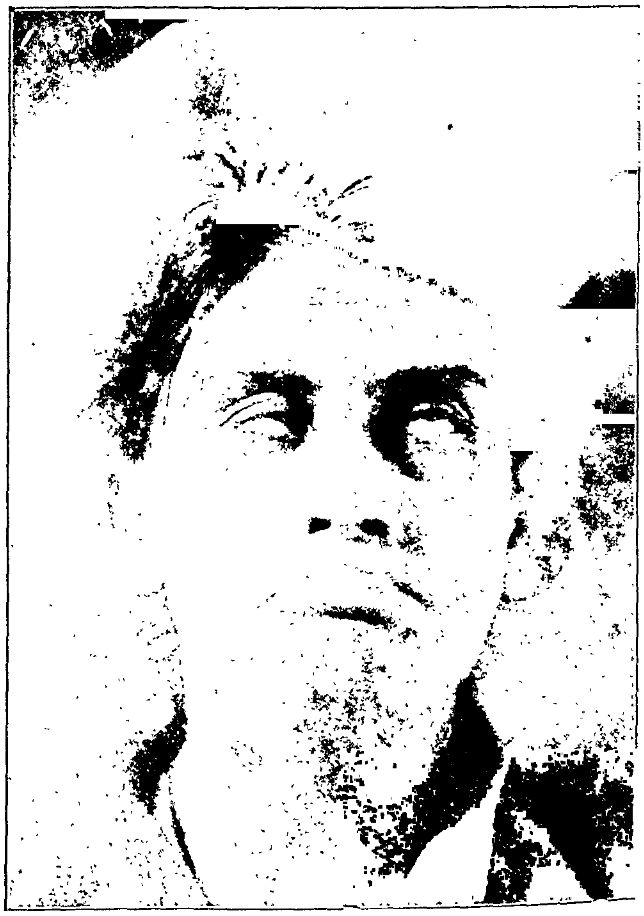
It was not until 1887, however, that the disease was first described in France by Terrillon,[2] and in America it seems even yet to be rare, for comparatively few reports of cases are on record. The best American paper is by Willard,[3] of Philadelphia, who, in 1895, published the report of a case in a boy and collected references in the whole literature to seventy-four cases, his own being the seventy-fifth. There are few other cases which have appeared since Willard published his paper or which escaped his observation.

In the vast majority of all reported cases the paralysis of the facial nerve has been unilateral, and this paralysis has been almost, if not quite, always on the side of the wound. A very few cases, however, of double facial palsy have been noted—so few, indeed, that I have found but six, possibly seven, examples. In these few cases, the wound, with but one exception, had been in the median line, usually on the nose, or on the bridge of the nose, or on the forehead. The case which is reported in the present paper is an instance of this double facial palsy, or facial diplegia, occurring in cephalic tetanus; and, as it is possibly only the seventh, or at most eighth, case of the kind to be observed with care, it has been deemed worthy of a special report.

Patient.—Mrs. K. O., aged 41, white.

History.—The patient first came to the Methodist Episcopal Hospital on Sunday, May 28, giving a history of having fallen downstairs eighteen days previously and having sustained an open wound on the bridge of the nose. The nose was swollen for a day or so, and the wound was covered with a small piece of court plaster. The patient felt no disability from the injury, except the discomfort from the wound, until fourteen days later, when she noticed her face beginning to draw toward the right side. She gradually became unable to move her lips, or to separate her jaws, and dysphagia soon developed.

Examination.—On examination by the resident physician, the following conditions were noted: The face was smooth and "ironed out;" the patient was unable to close her eyes, to wrinkle her forehead, to move her lips, to open her jaws or to swallow without difficulty. If the lips were held open by her fingers, she could articulate imperfectly; otherwise she answered in grunts. Sensation over the distribution of the fifth nerve was normal. The patient returned on the following Tuesday, when Dr. Holmes, under nitrous-oxid gas, found a spasm of the muscles of mastication, but no surgical condition present. The patient's friends said that she was able to close her eyes, to open her mouth, and to swallow until two weeks after the injury.



This shows the patient in the attempt to close the eyes. It also shows the trismus and the slight wound on the median line of the nose from which the infection occurred. The smooth expressionless appearance of the face and brow is also shown.

When the patient was examined by Dr. Lloyd, on June 2, the conditions were noted as follows:

The head is freely movable in all directions; no retraction of the head; no paralysis in any limb. A wound on the bridge of the nose is covered with a scab. The patient does not talk clearly, but answers mainly in grunts. She claims that she is able to swallow, but complains of the accumulation of saliva and phlegm in the throat. She swallows water at request when it is given slowly through a space left by an extracted tooth, the patient lying on her back during the process. The larynx does not seem to rise as fully as in the normal act of swallowing.

[1] Handbuch der Chir., von Pitha and Billroth, vol. 1, Ab. 11, No. 11, p. 5.

[2] Rev. de Chir., 1888, No. 1.

[3] Trans. Col. of Phys. of Phila., 1895, p. 27. Willard refers to a previous case reported by Hunt. (Trans. Col. Phys., Phila., 1862, May 7, vol. 111, N. S. p. 466), but Hunt's case was not one of cephalic tetanus. It was a case of punctured wound of the cranium, with injury to the brain, causing hemiplegia. The patient died of general tetanus, not kopftetanus with facial palsy.

Third, Fourth and Sixth Nerves: There is no involvement of any one of these nerves. Both the exterior and interior muscles of the eye act normally. The balls move freely in all directions. The pupils react normally to light and on accommodation and convergence.

Fifth Nerves: There is no anesthesia in the distribution of the fifth nerves. In the effort of chewing there is very slight movement of the masseters and temporals, but not enough to move the jaw, which is firmly set; and these muscles are felt to be rigidly contracted.

Seventh Nerves: There is slight ability to raise the right corner of the mouth. There is no sardonic grin, no tetanic rigidity of the facial muscles. In the act of trying to close the eyes, the balls roll far upward, but the orbicular muscles do not move, and the lids do not cover the whites of the eyes. There is no wrinkling of the brow. When laughing, there is no expression of the features indicating that act. The patient is unable to whistle, to puff out the cheeks, or to show the teeth. All the muscles of both sides of the face are paralyzed, except for the slight movement in the right corner of the mouth. The paralysis of both facial nerves is thus seen to be classical. The upper and lower fibers are alike involved. Both orbicular muscles are paralyzed; the patient can not close her eyes, and when she attempts to do so the eyeballs roll far upward until the corneæ are concealed beneath the upper lids. The brow and face are smooth and motionless, and the lips are powerless. The mask-like, expressionless appearance of the face is striking.

Twelfth Nerves: The patient claims that she can move her tongue; but this act can not be seen, because of the spasm of the jaw.

The trismus is extreme. The jaws are firmly set, and the patient can not separate the teeth to the slightest extent. In making an effort to talk she uses her fingers to separate the lips, which are flaccid and powerless. There is no tetanic involvement of the muscles of the neck, trunk, or limbs. No retraction of the head nor opisthotonus is present, or has been present.

The patient has no paralysis of the extremities. She is able to use her hands and arms perfectly, and walks with a natural gait; in fact, she walked into the hospital. The general condition is good; pulse and temperature are normal.

Course of the Disease.—The patient declined to remain in the hospital, and returned to her home, where she was treated by her family physician, Dr. William Irwin, to whose kindness I am indebted for the opportunity of continuing to see the case until the end.

June 7, the patient is slightly better. The eyes shut a little better, otherwise the symptoms are about the same. When she tries to talk, which she does very imperfectly, she holds the paralyzed lips apart with her fingers in order to enunciate more clearly (a characteristic action which has been noted in several of the reported cases). She is much annoyed by the accumulation of saliva, which tends to escape from between the paralyzed lips. The trismus is still complete; the lower jaw is clamped rigidly to the upper and is motionless. The patient is fed with fluids through a space left by an extracted tooth. There is to-day no true dysphagia or suffocation on swallowing, although from the statement of her attendants there has been something of the kind at times. There is no extension of the tetanic spasms to the neck, trunk or limbs. There is no paralysis of the limbs; the knee jerks are slightly increased, also the biceps jerks. There is no Babinski, or Oppenheim, or McCarthy reflex. The attempt to laugh produces a curious result; there is an odd sound, as of a chuckle, in the throat, but the face remains motionless. The general condition is fairly good; pulse 100; temperature normal.

June 16, examination with Dr. Irwin. The patient is better. She has regained some power in the face, more on the right side, and is able to draw the corner of the mouth farther over to that side. She is still unable to shut her eyes, to wrinkle her brow, to whistle, or to laugh. There is some relaxation of the jaw, as is seen on attempts at chewing, and as is proved by the fact that the patient has bitten her tongue. This also proves that she is able to move her tongue. The lower jaw, nevertheless, is still very rigid. There are no ocular palsies, or fifth nerve palsies, sensory or motor. There is no spasm on deglutition, nor of the neck or trunk. Saliva still tends to dribble from between the lips. General condition is good. The treatment by Dr. Irwin has been with chloral and the bromids. No antitetanus serum has been used at any time in the case. The prognosis seems very favorable to-day.

July 3, the patient has improved greatly, and has been out to walk. She can shut her eyes, wrinkle her forehead and whistle, but the lower fibers of the seventh nerves are still somewhat involved, more than the upper. The jaw is much relaxed, but still a little stiff. The eye muscles are normal. The expression of the face on laughing is still peculiar. The patient can be pronounced convalescent.

From this time the progress of the case was steadily onward to recovery. The whole duration of the tetanus was about six weeks.

CHIEF FACTS OF NOTE IN CEPHALIC TETANUS.

The following are some of the main facts to be noted in cases of cephalic tetanus:

The Seat of the Wound.—In the majority of cases of cephalic tetanus, the facial paralysis has been one-sided, and the wound, too, has been on one side, the paralysis being on the same side as the wound. Exceptions to this rule have been rare, and even open to doubt. A wound on the right side of the face does not cause facial paralysis on the left side, or *vice versa.* In all the cases of facial diplegia, however, except that of Roberts', the wound has been in the median line of the face, nose or forehead, but not every wound in the median line has produced bilateral symptoms, as witness the cases of Nankevell[4] and Oliva,[5] in which the wound was on the bridge of the nose, but the facial paralysis was on the right side of the face only; the case of Wagner,[6] in which the wound was in the center of the forehead, and that of Nerlech,[7] in which the wound was at the root of the nose; but in both cases the paralysis was in the distribution of the left facial nerve. By far the greater number of observers place the paralysis on the same side as the injury. On whichever side it occurs, however, the wound in cephalic tetanus is in the area of distribution of the fifth nerve, the commonest point being in what some authors call the orbital-nasal-temporal angle. One case has been reported, that of Pollock, in which the wound was in the eyeball, and another in which it was in the mouth. In the few cases in which the muscles of the eye have been paralyzed, the wound has been on or near the lid, but not all cases of wound on or near the lid have caused ocular paralyses.

The Character of the Paralysis.—The paralysis of the seventh nerve has all the characteristics of a peripheral paralysis; hence, it is like a genuine Bell's palsy. Both the upper and lower fibers are involved. The brow, the orbicularis palpebrarum, the small muscles of the face and lips, all are involved. Consequently, the patient can not wrinkle the brow, close the eye, move the face or lips, whistle, or display the teeth; and in unilateral cases the characteristic deformity is present, as caused by the flattening of the nasal fold and the drawing of the face toward the sound side. For some unknown reason, however, the reactions of degeneration are not present.

[5] Gaz. de Chir., 1886.
[6] Schmidt's Jahrbuch, 1881, p. 139.
[7] Inaug. Dissert., Halle, 1892.

The Tetanic Symptoms.—Trismus is always a marked symptom, and in some cases it is the chief or even the only tetanic symptom. In not a few cases nowever, the tetanus extends to other muscles, as of the throat, neck, trunk, and limbs, the case thus presenting the picture of a more or less general tetanus. As a rule, however, the symptoms of cephalic tetanus are not so widespread or severe as in the ordinary type—a fact which bears on the prognosis.

Paralysis of Other than the Facial Muscles.—In a very few reported cases, the muscles of the eyes have been paralyzed. Thus, in Roberts' case, the left eyeball was completely immobile, while in the right orbit only the third and fourth nerves were paralyzed, the sixth escaping. The wound was under the left eye. In one case,[8] ptosis was observed. Willard makes no reference to these complications, so they are probably rare. v. Schrötter[9] reports a case of *kopftetanus* in which there was paralysis of the facial, the ocular, and the hypoglossal nerves. Neumann[10] claims that the facial nerve is paralyzed first: then the oculomotor, abducens, trochlear and hypoglossal are affected in the order named; but the number of reported cases is too small to admit of such a dogmatic rule. In most cases, the paralysis of the facial nerve has appeared at about the same time as the lockjaw.

PROGNOSIS.

Cephalic tetanus is not quite so severe a disease as the ordinary type of tetanus. More patients recover than in the usual form of lockjaw. Nevertheless, it is a very grave affection, with a high death rate, as the reported cases prove. From Willard's table we learn that of 45 "acute" cases (counting those as acute in which the lockjaw supervened within the first week after the wound) 39 patients died and only 4 recovered, a mortality of 90 per cent. Of 32 "chronic" cases (after the first week), 8 patients died and 24 recovered, a mortality of 25 per cent. This difference is striking and shows very conclusively that the important factor in prognosis is the date of onset of the tetanus after the reception of the wound. Gowers has claimed that the age of the patient is the determining factor; that all cases in patients over 25 years of age are fatal; but Willard's table disproves this claim effectually, for 15 of the patients who recovered were over 25 years of age. In the case reported in this paper, the patient was 41 years old and made a good recovery, but she comes within the "chronic" group, for the lockjaw did not appear until the fourteenth day. Willard's table also proves that in the "local" cases, i. e., those in which the tetanic symptoms are confined to the jaw, throat and neck, the prognosis is better, for 14 patients recovered and 15 died; while of the "general" cases, in which the tetanus is widespread, 14 patients recovered and 32 died. This is in accord with what might be expected. In the present case, the tetanus was strictly limited to the jaw, and the patient recovered, her condition never presenting such a grave appearance as is seen in generalized tetanus. On the other hand, the majority of the cases of facial diplegia have been fatal; in the 7 cases noted, only 2 patients recovered, one of them being my case; but these fatal cases also have all been in the "acute" group.

REVIEW OF THE CASES IN THE LITERATURE.

The following are brief statements of the cases of facial diplegia in cephalic tetanus that have been collected:

Thenée's Case.[11]—The wound was on the root of the nose, hence probably in the median line. It is reported as a case of "one-sided trismus," but there was also paralysis of the left side of the face, followed by paralysis of the right side. It proved fatal on the ninth day after the wound.

Roberts' Case.[12]—The wound was under the left eye, with early onset of tetanus and general convulsions. The left facial nerve was paralyzed completely, also the upper distribution of the right facial nerve. The left eye was completely immobile, while on the right side the third and fourth nerves were paralyzed, the sixth escaping. The case was fatal.

Huntingdon's Case.[13]—The wound was a little above the root of the nose—hence, probably in the median line. There was complete bilateral facial paralysis, but no orbital paralyses. Dysphagia was present, with profuse salivation. Trismus and cramps in the legs and trunk muscles occurred. Recovery took place in six weeks.

Bourgeois' Case.[14]—This patient was a gardener. The wound was in the median line on the nose. Both seventh nerves were totally paralyzed. Convulsions were general; the patient had dysphagia and spoke with difficulty, using his fingers to open his lips. The onset of the tetanus was on the sixth day, and death occurred on the third day after the first appearance of the lockjaw.

Crouzon's Case.[15]—The wound was in the median line at the root of the nose, and both seventh nerves were paralyzed. The patient used his fingers to separate the paralyzed lips in speaking. The case terminated fatally on the thirteenth day from the reception of the wound, the convulsions having become general.

Bouchaud's Case.[16]—The patient was a gardener. The wound was on the nose in the median line. The patient could not swallow liquids and spoke with great difficulty. Both seventh nerves were totally paralyzed, the paralysis being of the peripheral type. There was possibly some weakening also of both superior recti muscles of the eyes. Slight power remained in the lips. (Does this indicate that the lips are partially innervated by the twelfth nerves?) The patient, as in other cases, used his fingers to separate the lips in attempting to speak. Attempts at swallowing brought on suffocation. There were no tetanic spasms in the neck, trunk or limbs. An interesting feature was the fact that the patient was an epileptic, and had one epileptic seizure during his illness; but unfortunately it was not noted whether the paralyzed facial muscles were convulsed during this fit. The tetanus appeared on the sixth day after the wound, and death occurred six days later.

Caretti's Case.—Bouchaud refers to a case of facial diplegia in cephalic tetanus, reported by Caretti, but I have not secured the report of this case.

COMMENTS.

There has been much speculation about the nature of the paralysis of the facial nerve in cephalic tetanus. It is a unique phenomenon, for tetanus does not cause paralysis in other parts of the body. As these cases all occur from wounds in the area of distribution of the fifth nerve, the hypothesis of a reflex paralysis has been invoked, but it explains nothing. Tetanus is an infectious disease, caused by a microbe. This microbe gains entrance in these cases at a point where it can exert a direct action on the seventh nerves, and its effect is to paralyze one set of nerve fibers (the seventh) while it causes tetanic spasm in neighboring nerves (the motor branches of the fifth). It might well be called *tetanus paradoxus*. Some observers have claimed that the trismus also has a tendency to be unilateral, or at least more marked on the side of the wound.

Vaillard (quoted by Bourgeois) denied that the facial nerve is truly paralyzed in these cases; he seemed to think that it was in tetanic spasm. It has been suggested that the asymmetry of the face is not due to paralysis, but to excessive tetanic spasm in the muscles of the opposite side.[17] Such an explanation, however, falls completely to the ground in those cases in which both facial nerves are paralyzed. Moreover, it can not explain the typical inability to close the eye and to wrinkle the brow and all the other classical symptoms of Bell's palsy. It has also been suggested (by Bernhardt and by Guterbrock) that the paralyzed muscles are also contractured; but this does not appear to be so on close examination. The passive raising of the lips by the breath on expiration and the lifting of the flaccid lips by the fingers in attempts at speaking (a characteristic act) are clearly indicative of paralysis.

Some of the clinical observations here recorded have been confirmed by experimental work, especially with reference to the seat of the wound. Brunner[18] injected the tetanus toxin into guinea-pigs and obtained symptoms on the same side into which the toxin was injected; and if it was injected into the median line, the symptoms were bilateral.

The pathology of this facial paralysis in cephalic tetanus has not been satisfactorily determined, although a number of autopsies have been made. The results, however, are negative. The reactions of degeneration have not been obtained. This was so in Willard's case, in which I made the tests. In the case reported in this paper the opportunity to make an electrical study was not favorable.

There has been no attempt in this paper to go into an exhaustive review of the literature. Willard's paper, already quoted, gives a long list of references and it is easily accessible. The attempt has been made here, however, to collect all the cases in which the facial paralysis was bilateral. Willard, in a review of 75 cases of cephalic tetanus, found but 2 in which both seventh nerves were involved. With the assistance of Dr. C. D. Camp, I have studied about 25 additional cases of cephalic tetanus, found but 2 in which both not included in Willard's list, and have found a total of 7 cases of facial diplegia, as abstracted above, the present case being the eighth.

Important papers on the subject of cephalic tetanus are by Villar,[19] Bernhardt,[20] Dard,[21] and Sapincourt,[22] the last two of which have not been accessible to me.

ATAXIA OF CENTRAL ORIGIN APPEARING IN CHILDHOOD.*

ARTHUR WILLARD FAIRBANKS, M.D.
BOSTON.

This paper is a brief consideration of a form of central nervous disease previously described under the titles of hereditary ataxia, cerebellar ataxia, and not infrequently under the heading of Friedreich's disease. It varies, in certain particulars, however, as we shall see, from the usual conception of what should constitute the affection bearing Friedreich's name. In view of its relative rarity, the number of cases of this affection coming under the observation of any single observer is naturally small.

The clinical characteristics of this affection stated briefly are: Muscular inco-ordination commencing usually in childhood, and, as a rule, first affecting the muscles of the lower extremities, thence extending to the upper extremities, and to the muscles of the trunk, head, larynx, tongue and eyes; slowness of muscular response to volitional impulse; swaying, unsteady gait; slow, hesitating or deliberate speech, sometimes of nasal character and occasionally explosive; nystagmus; oscillation or tremor of head, body or extremities; and certain involuntary movements, which may or may not be of choreiform character, and which may occur independently or may be associated with volitional intended movement of some other part of the body; lateral curvature of the spine; deficient energy in carrying out voluntary movements; and, in an advanced period of the disease, paralysis, muscular spasm and contractures.

To this symptom-complex may be added, during the course of certain cases, various other symptoms not sufficiently invariable to be considered characteristic, but nevertheless to be regarded as inherent, although less common, phenomena. Among these may be mentioned vertigo, headache, optic atrophy and impairment of pupillary action and of the movements of the ocular muscles, apathy of facial expression, a tendency to involuntary and unprovoked laughter, loss of muscular tone, sensory disturbance, peculiar deformity of the feet, trophic changes in muscles, and very rarely interference in the action of the sphincters and trophic changes in the skin.

Certain other phenomena must be regarded in the light of complications, since they are clearly due to involvement of those parts of the central nervous structure, primary affection of which would produce a clinical picture totally different from the one we are considering.

Such is the occurrence of psychical phenomena, depreciation of intellectual power, or epileptiform attacks. In this symptom-complex will be recognized many of the symptoms that characterized the well-known cases described by Friedreich in 1861, and which have since been identified with his name. Since then many cases have been reported differing so widely from the type originally described that certain observers have been led to believe that they were dealing with an affection of different nature. Several of these cases were undoubtedly not instances of Friedreich's disease, and even in the light of our present knowledge of how manifold may be its symptom-complex, bore in their clinical characteristics no resemblance whatever to the affection. The

* Read in the Section on Diseases of Children of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

this column of the gray matter of the cord have been affected in nearly every instance where a pathologic examination has been made, make it exceedingly probable that Clarke's column was involved.

If, therefore, we may include this case, we find this column also affected in every one of these five cases. In every case the posterior nerve roots were more or less degenerated. The central canal is usually blocked with cells and its epithelial lining lost. In addition to these well-defined lesions, slight changes were found in individual cases in the rest of the gray matter and in the anterior roots. In two instances the crossed, in one the direct, pyramidal tracts were involved in the degenerative change. In all but one of these cases there were found abnormal conditions of the medulla and cerebellum, consisting of a reduction in size as a whole, atrophy of medullary fibers belonging to the cerebello-spinal system, and in two instances fibers of the cerebello-cerebral tract in the brachia conjunctiva, and atrophic changes and reduction in size and number of the ganglion cells of the gray matter, including in Menzel's case some of the cranial nerve nuclei, the spinal accessory, hypoglossal, facial, and the motor nucleus of the fifth.

The finer changes are characterized by a loss of the medullary sheaths, a shrinking and granular degeneration of the ganglia cells, by a proliferation of the neuroglia and an increase in the glia cells. In other words, by a parenchymatous degeneration and an interstitial proliferation.

While it is not my intention, in this brief paper, to discuss the etiology of this affection, it is nevertheless of the greatest interest to note that that portion of the cord, at least, which is the seat of the greatest intensity of the process is that part which is formed last, and which is nearest in point of time, and perhaps in condition, to the embryonic state, namely, the columns of Goll, Clarke and Burdach. Of the elements composing their structure, the matrix, or neuroglia, remains the nearest to the embryonal state. The tendency of embryonic or immature tissue to proliferate, in response to trauma or other irritant, is well known. It may be that the primary step in this affection is a proliferation of the neuroglia, followed by a degeneration of the medullary fibers, which are, perhaps, through their immaturity or inherent lack of vitality, only too ready to degenerate.

The sclerosis of the direct cerebellar tract is, I think, to be regarded as purely secondary to the atrophy and disappearance of the cells of the column of Clarke, and that, whatever part the neuroglia may elsewhere play in the process, it is here increased only as a result of the loss of the medullary fibers.

Just why the pyramidal tracts should degenerate as they have in certain cases is much more difficult to answer. It seems possible to me that, in cases where there is extreme proliferation of the neuroglia in the region of the transverse fibers of the pons, the pyramidal tracts may be injured as they pass through these transverse bundles from the middle cerebellar peduncle. This does not explain, however, those instances where the pyramidal fibers in the cord alone are implicated, with no involvement above their decussation. Interesting, however, is the occurrence of ascending degeneration of these tracts in certain cases of gliosis and cavity formation in the cord. Here it is, also, of interest to note the singular proneness of Clarke's column to degenerate in these cases of syringomyelia, and the much greater frequency of involvement of the posterior columns in the gliosis and secondary degeneration in this affection.

Proliferation of glia tissue, in cases associated with structural defects, either congenital or acquired, in the cord, is, of course, well known. Of the greatest interest it seems to me, in this connection, is the fact that structural abnormalities of the cord have been found several times in Friedreich's disease; in fact, in one of the cases reported by himself two symmetrical canals were found in the lower dorsal region nearly corresponding to the columns of Clarke on each side; and in a case reported by Mackay, a picture of which I hope to show you later, marked structural anomaly was present. In our series, in Smith's case, an abnormal canal was present in the lumbar region. These defects lend strong support to the view that we have to do with, a process supervening on a developmental insufficiency, either in structure or inherent vitality, of the nervous system. This view is still further strengthened by the frequent strong family tendency to the disease, by the occasional history of its occurrence in other generations, and by the not infrequent presence in other members of the family, not affected by the disease, of marked anatomic, physiologic or psychical defects. Marie, in 1893, attempted to establish a differentiation of certain cases from Friedreich's disease on the basis of a difference in the clinical symptoms, laying especial stress on the age of onset and the condition of the knee jerks. A study of a large number of instances of the symptom-complex does not seem to support the contention.

The variations in the phenomena are seen to be merely a question of degree, the variations so merging into one another as to allow of no abrupt distinction. Neither do the results of pathologic examination permit of any sharp differentiation. Even in one of the first cases ever reported we find invasion of the lower portion of the medulla; in others the upper part as well; in still others implication of the pons and cerebellum. Moreover, some of the symptoms of Friedreich's disease are distinctly cerebellar in character, and, while I do not believe it essential that the cerebellum be affected for the production of these phenomena, they being also possible in disease of its connections with the rest of the nervous system, I believe it would be found affected much more frequently if microscopic examination of its structure was made.

Moreover, many of the phenomena of our symptom-complex have occurred in cerebellar atrophy, hemorrhage and other lesions, in the human being, and have been features of the phenomena following atrophy or experimental lesions of the cerebellum in animals. I regret that the time does not permit giving the details of these instances.

I may mention, however, among many other interesting instances, the results of the experiments of Luciani, in Italy, in which partial or complete extirpation of the cerebellum, in monkeys and dogs, was followed by mus-
cular inco-ordination, loss of muscular energ of the dis-
muscular tone, tremor and oscillations of climatic and
of the body, curvature of the spine, for favorable for its
of the body, slowness of voluntar which there are more
mus and muscular contractur ever before. The method
are frequently met with in respects similar to, and is
most of which are almost during the American occupa-

Dr. C. F. Wahrer, been sufficiently demonstrated, in
choreic movements 1905, that under the lax system here-
movements of th in vogue, yellow fever can easily secure

majority, although varying in certain features, are, for the most part, so strikingly similar that no doubt of their close relationship can be entertained. Neither Friedreich's cases nor any other of the early instances reported can be used as a standard either on the basis of their clinical or pathologic character. An adequate idea of the affection and its variations can only be obtained by a study of many cases at different stages of the process and by careful comparison of the clinical phenomena with the changes found in the central nervous structure where systematic pathologic examination has been made.

Not all the symptoms of the affection develop in its early stage. Several are late phenomena. Naturally, therefore, the number of typical symptoms presented by any given case depends, in great measure, on the duration of the affection. Then some of the later symptoms tend to mask or obscure the earlier phenomena and thus alter the clinical picture. Finally, much depends on the extent of the process in the central nervous structure. Obvious as these facts may seem, they have not been given due consideration by many observers. In this connection I venture to assert my belief that the condition of the tendon reflexes, so long a bone of contention between the adherents for and against the maintenance of Friedreich's original type, is solely a matter of the duration, location or extent of the central lesion; and that the presence or absence of the knee jerks is, in itself alone, of no differential diagnostic value in this affection, and only indicates to us whether the process has or has not involved certain definite portions of the nervous structure.

Several cases, all in the early stage, because seen in young children from 3 to 10 years of age, have come under my observation. Five concern children 4 and 5 years old, in all of whom the affection was noticed first when the child began to walk, by its failure to acquire the power of equilibration. The brevity of the time allowed unfortunately forbids the giving of these cases in detail.

In all of these five cases the gait was unsteady; in three extremely so, these children walking with feet wide spread, from time to time hesitating, halting in their forward progress to sway several seconds over their center of gravity, as if about to fall, then moving forward, often with several short, quick steps in their effort to maintain their balance, approaching their objective point in a more or less indirect course.

In three of the five, well-marked ataxia of both upper and lower extremities was present, and was in all much more marked in arms and hands than in legs. In two speech was affected, in one associated with distinct involuntary accessory movement of lower facial muscles; in two speech was not acquired; in the fifth it was not yet abnormal. None of the other symptoms have yet appeared.

These cases are mentioned together because of the early period at which they came under observation, but also because in no single instance were the knee jerks lost.

For the privilege of reporting these cases I am greatly indebted to Dr. Bullard and to Dr. Thomas, from whose clinic at the Children's Hospital the cases come.

To these I wish to add a child of 10 years, which I saw in Senator's clinic, in which the knee jerks were greatly increased, and, in addition to the above well-marked symptoms, choreiform movements of head and arms and nystagmus were present.

The six cases reported by Friedreich in 1861 presented many, though not all, of the features of our symptom-complex. Being the first cases to be clearly recognized as a clinical entity, apart from the ataxy of Duchenne, and so reported and carefully described, they attracted wide attention and were discussed everywhere. This universal interest, fostered by several later papers by Friedreich, and increased by subsequent reports of apparently analogous cases by other observers, soon led to the adoption of Friedreich's name as the synonym of the disease. Then appeared, on the part of certain writers, an attempt to construct a rigid standard, based on the symptoms of Friedreich's cases and of those reported soon after his article appeared, to which it was required that all cases should conform. For a brief period all went well. Soon, however, as the field of observation enlarged, there began to appear instances differing materially in features of their symptom-complex from the clinical picture considered by these observers as characteristic of Friedreich's disease.

Cases appeared, the apparent origin of which was not at puberty, but much earlier; others also appeared of later origin. In some the knee jerks were not absent, but present, and even increased. Impairment of vision, disturbance in action of the pupils and external ocular muscles and other evidence of cranial nerve involvement occurred, while the not very infrequent presence of disturbances of sense gave evidence of occasional participation on the part of the sensory sphere.

Among these instances and possessing nearly all of the phenomena of our symptom-complex in most pronounced degree are the cases reported by Everett Smith, Menzel, Nonne and Sanger Brown. These cases are of exceptional interest on account of the extreme degree the affection attained and the frequent occurrence of the more unusual symptoms, and especially bulbar phenomena. Smith's cases are of special interest to us, because of five children affected in a family of thirteen the affection began in four before the tenth year. Of the greatest importance, however, is the fact that we have, in certain cases of each series, the records of the pathologic changes at the basis of this symptom-complex.

Six autopsies are presented for our consideration. Nonne's case showed general smallness of the entire nervous system without signs of degeneration. This case as reported is an anomaly. If this was, as Nonne thinks, a congenital condition, it can not be explained why the symptoms did not become marked until well along in adult life, and then were markedly progressive up to time of death.

In all of the other cases extreme degeneration of the posterior columns of the cord was found, together with marked involvement of the direct cerebellar tract (if we assume, as seems to me probable, and as I think the plate of the cross-section of the cord indicates, that a part of the degenerated fibers, in the lateral columns of Smith's case, were fibers of this tract). The condition of Clark's column is also unfortunately not mentioned in this case. It is, however, specifically stated that cells of the gray matter were far less numerous than usual, especially in the posterior portion, and in some places only a scattered few were to be seen. This, taken into consideration with the fact that the cells and fibers of this column of the gray matter of the cord have been affected in nearly every instance where a pathologic examination has been made, make it exceedingly probable that Clarke's column was involved.

If, therefore, we may include this case, we find this column also affected in every one of these five cases. In every case the posterior nerve roots were more or less degenerated. The central canal is usually blocked with cells and its epithelial lining lost. In addition to these well-defined lesions, slight changes were found in individual cases in the rest of the gray matter and in the anterior roots. In two instances the crossed, in one the direct, pyramidal tracts were involved in the degenerative change. In all but one of these cases there were found abnormal conditions of the medulla and cerebellum, consisting of a reduction in size as a whole, atrophy of medullary fibers belonging to the cerebello-spinal system, and in two instances fibers of the cerebello-cerebral tract in the brachia conjunctiva, and atrophic changes and reduction in size and number of the ganglion cells of the gray matter, including in Menzel's case some of the cranial nerve nuclei, the spinal accessory, hypoglossal, facial, and the motor nucleus of the fifth.

The finer changes are characterized by a loss of the medullary sheaths, a shrinking and granular degeneration of the ganglia cells, by a proliferation of the neuroglia and an increase in the glia cells. In other words, by a parenchymatous degeneration and an interstitial proliferation.

While it is not my intention, in this brief paper, to discuss the etiology of this affection, it is nevertheless of the greatest interest to note that that portion of the cord, at least, which is the seat of the greatest intensity of the process is that part which is formed last, and which is nearest in point of time, and perhaps in condition, to the embryonic state, namely, the columns of Goll, Clarke and Burdach. Of the elements composing their structure, the matrix, or neuroglia, remains the nearest to the embryonal state. The tendency of embryonic or immature tissue to proliferate, in response to trauma or other irritant, is well known. It may be that the primary step in this affection is a proliferation of the neuroglia, followed by a degeneration of the medullary fibers, which are, perhaps, through their immaturity or inherent lack of vitality, only too ready to degenerate.

The sclerosis of the direct cerebellar tract is, I think, to be regarded as purely secondary to the atrophy and disappearance of the cells of the column of Clarke, and that, whatever part the neuroglia may elsewhere play in the process, it is here increased only as a result of the loss of the medullary fibers.

Just why the pyramidal tracts should degenerate as they have in certain cases is much more difficult to answer. It seems possible to me that, in cases where there is extreme proliferation of the neuroglia in the region of the transverse fibers of the pons, the pyramidal tracts may be injured as they pass through these transverse bundles from the middle cerebellar peduncle. This does not explain, however, those instances where the pyramidal fibers in the cord alone are implicated, with no involvement above their decussation. Interesting, however, is the occurrence of ascending degeneration of these tracts in certain cases of gliosis and cavity formation in the cord. Here it is, also, of interest to note the singular proneness of Clarke's column to degenerate in these cases of syringomyelia, and the much greater frequency of involvement of the posterior columns in the gliosis and secondary degeneration in this affection.

Proliferation of glia tissue, in cases associated with structural defects, either congenital or acquired, in the cord, is, of course, well known. Of the greatest interest it seems to me, in this connection, is the fact that structural abnormalities of the cord have been found several times in Friedreich's disease; in fact, in one of the cases reported by himself two symmetrical canals were found in the lower dorsal region nearly corresponding to the columns of Clarke on each side; and in a case reported by Mackay, a picture of which I hope to show you later, marked structural anomaly was present. In our series, in Smith's case, an abnormal canal was present in the lumbar region. These defects lend strong support to the view that we have to do with, a process supervening on a developmental insufficiency, either in structure or inherent vitality, of the nervous system. This view is still further strengthened by the frequent strong family tendency to the disease, by the occasional history of its occurrence in other generations, and by the not infrequent presence in other members of the family, not affected by the disease, of marked anatomic, physiologic or psychical defects. Marie, in 1893, attempted to establish a differentiation of certain cases from Friedreich's disease on the basis of a difference in the clinical symptoms, laying especial stress on the age of onset and the condition of the knee jerks. A study of a large number of instances of the symptom-complex does not seem to support the contention.

The variations in the phenomena are seen to be merely a question of degree, the variations so merging into one another as to allow of no abrupt distinction. Neither do the results of pathologic examination permit of any sharp differentiation. Even in one of the first cases ever reported we find invasion of the lower portion of the medulla; in others the upper part as well; in still others implication of the pons and cerebellum. Moreover, some of the symptoms of Friedreich's disease are distinctly cerebellar in character, and, while I do not believe it essential that the cerebellum be affected for the production of these phenomena, they being also possible in disease of its connections with the rest of the nervous system, I believe it would be found affected much more frequently if microscopic examination of its structure was made.

Moreover, many of the phenomena of our symptom-complex have occurred in cerebellar atrophy, hemorrhage and other lesions, in the human being, and have been features of the phenomena following atrophy or experimental lesions of the cerebellum in animals. I regret that the time does not permit giving the details of these instances.

I may mention, however, among many other interesting instances, the results of the experiments of Luciani, in Italy, in which partial or complete extirpation of the cerebellum, in monkeys and dogs, was followed by muscular inco-ordination, loss of muscular energy the dis-
muscular tone, tremor and oscillations of climatic and
of the body, curvature of the spine, favorable for its

these children. The only case Dr. Garrison has seen which resembled it was a 5-years-old child whom she was called to see. A consultation had been held and the child was to be operated on for tubercular peritonitis. Dr. Garrison found the child completely paralyzed except in the left hand. She objected to the operation, for she saw no signs of tubercular peritonitis, and asked the physician to examine for tubercular organisms in the sputum and a few bacillus were found. The child, three months afterward, visited Dr. Garrison and remained for three weeks. When she came she was able to creep around. By judicious manipulation the development of the atrophied muscles was aided and the child is now apparently in perfect health and has since been able to enter school.

Dr. A. W. Fairbanks said that the movements noted were not those of *tic convulsif*. The athetoid movements did occur, but so rarely that he did not include them in his summary of the signs. He is inclined to think that they were not athetoid movements, but rather choreic movements of slow character, simulating athetoid movements. There was extreme atrophy and degeneration of the peripheral nerves. Dr. Fairbanks thinks that there is no ground for the assumption that tuberculosis is an etiologic or pathologic factor. Tubercular processes are sometimes terminal factors of the disease, but do not form an integral part. He should not consider that the case mentioned by Dr. Garrison belongs to this class of disease because of its marked improvement. Instances do occur in which the disease does not progress for a time, but sooner or later it progresses and the patient dies. He believes that the more these cases are studied the more it will be found that they originate in childhood. The very slowly progressive symptoms in the early stages are overlooked by the parents.

COLLODION AS A DRESSING AFTER INTRANASAL OPERATIONS.

A PREVENTIVE OF POST-OPERATIVE HEMORRHAGES.*

KASPAR PISCHEL, M.D.
SAN FRANCISCO.

Since the publication of my first paper on this subject,[1] some improvements have been made in my method of using collodion as a dressing after intranasal operations. These were partly evolved from my own experience and partly from the suggestions of my colleagues.

Dr. E. Rixford of San Francisco suggested the use of compound tincture of benzoin as a substitute for collodion. I found it very reliable as a preparation of the wound for collodion; it dries the tissue nicely, so that the collodion sticks to it much better.

Dr. James F. Smith of San Francisco uses pieces of gauze instead of wisps of cotton. I have followed his suggestion.

Dr. C. W. Richardson,[2] Washington, D. C., applies the collodion with a probe; I had tried that before I selected my present method, but discarded it.

That the usual after-treatment is not satisfactory to
many was well expressed lately at two European con-
yet abnor ere this question was discussed.
peared. take the liberty to describe my method.

greatly increased, and, in addition to the

I have now used this dressing in 243 cases with perfect results in 233 cases. I had to replace the collodion dressing after a few hours in 4 cases. In 3 of these the hemorrhage ocurred on the posterior end, in 1 case of polypoid degeneration of the erectile tissue in the anterior half. In 6 cases, or less than 3 per cent., the collodion dressing was not sufficient and had to be replaced by packing. The hemorrhages occurred in 5 cases from the posterior end of the lower turbinal. One of these five patients was a bleeder, with hypertrophy of the left ventricle, high blood pressure and traces of albumin in the urine, indicating the beginning of a shrinking kidney. The sixth case was a fibrous polypus from above the posterior end of the lower turbinal on a place on which I could not properly apply the collodion dressing.

I am aware that this method is far from perfect, but I hope that if some members of this Section take the matter up and try to improve on it they will perfect it to such a degree that there will be no more postoperative hemorrhages.

TECHNIC.

After I have finished the operation and stopped the bleeding with adrenalin, I clean the field carefully, wipe over the wound and surrounding tissue compound tincture of benzoin on a cotton carrier, then cover the wound with a piece of sterilized gauze (about 1 by 2 cm.). I am particularly careful to press this around the posterior end, as from that point hemorrhages occur most frequently. These pieces of gauze I keep on hand compressed, so that they are stiffer and can be more easily introduced. I drop the collodion slowly on this gauze, beginning on the posterior end, while my assistant blows hot or cold compressed air into the nostril to quicken evaporation. The collodion and gauze form a white, firm membrane, which fulfills two purposes: it protects the wound against infection from the air, and prevents secondary hemorrhage. As an extra precaution, I instruct the patient to keep a little cotton in the entrance of the nose on the way home. This absorbs the little oozing of blood and serum which exists even when the nose is packed. The cotton may be changed as often as it is soaked; but the patient may take it out at home so that he can breathe through that nostril. This dressing I leave in the nose from four to six days; if left longer the edges become loose and too much discharge is kept back.

In order to remove the dressing, I cocainize the nose and apply some peroxid of hydrogen, which helps to loosen the dressing, which I then take out with a pair of pincers; frequently a few drops of blood follow this procedure.

For dropping the collodion on the wound an ordinary eye dropper will not do. The collodion would flow too quickly. It must be dropped on the wound slowly and carefully, so that it does not run down into the pharynx, an accident which would make the patient gag and cough. One might use a fine Eustachian catheter, on the wider end of which a small rubber bulb is mounted, fastened airtight with a rubber band. One filling of the tube with collodion is usually enough to cover the whole wound. I use a small metal tube 9 cm long, 1 mm. thick, with a tulip tip on one end, to fasten the rubber bulb. This tube must be cleaned out thoroughly after use.

DISCUSSION.

Dr. Otto T. Freer, Chicago, regards dismissing patients after intranasal operations without tamponing as permissible after operations on the middle turbinated body, but a dan-

---

Otology of the
Annual Session,

gerous practice to follow after resections of the lower turbinate or operations on the septum. A false security is created by the long duration of the bloodlessness about the wound due to cocain and adrenalin, so that even a good-sized artery will not bleed. After some hours, however, relaxation of the vessel with dangerous bleeding is very apt to occur, and to last a long time before the surgeon can reach his patient. Dr. Pischel's method may be a good substitute for the tampon though Dr. Freer has had no experience with it, but to let the patient go without any precaution against delayed hemorrhage is a mistake. Dr. Freer said that he knows of a case in the practice of a colleague in which the patient bled to death in spite of packing, and of a hemorrhage in the practice of another physician in which the patient became almost exsanguinated before relief came. It is therefore not safe, he said, to send the patient home unpacked. The physician can not be sure that he will observe instructions and will not sneeze and blow the nose. Dr. Freer has seen a violent delayed hemorrhage follow the use of the galvano-cautery.

Dr. Hal Foster, Kansas City, Mo., said that if physicians err at all they would better err on the side of safety and use some packing in the nose. There may be many cases without hemorrhage, but they are likely to have an unpleasant experience at any time. He would feel safer with a packing in the nose.

Dr. Robert C. Myles, New York, said that the history of nasal operations resembles in some respects the work on the throat. Mackenzie did more operations without a death than probably any other man, and he had no hemorrhage. Dr. Myles has had several hemorrhages that were very distressing. He adopted the practice of putting nothing in the nose and got along very nicely until he would have a hemorrhage in the midst of a busy day, and then he would begin packing all of that class of cases. It is often advisable, he said, to remove large pultaceous masses of tissue from the anterior turbinate when these cause distress in sleeping and breathing or in the ear. The removal with snare, scissors or trephine, of the redundant tissue of the turbinate and the periosteum gives often permanent freedom, but hemorrhage frequently occurs. No doubt there are many evil consequences from packing and from the pressure. If patients could be controlled it would be better not to pack. Physicians pack in many cases in which, possibly, it is not needed, because of the danger of hemorrhage. When called to these cases of hemorrhage there is usually a great loss of blood before the physician arrives.

Dr. Kaspar Pischel, San Francisco, declared that just such experiences as Dr. Richards has described compelled him to use packing before 1901. In his own nose the packing was so disagreeable that he began to look for something else. He covers the whole wound with collodion. The same method is used after operations on the middle turbinate and on the septum.

LESSONS TO BE LEARNED FROM THE PRESENT OUTBREAK OF YELLOW FEVER IN LOUISIANA.*

JAMES CARROLL, M.D.
Assistant Surgeon, U. S. Army.
WASHINGTON, D. C.

The present seems to be a suitable occasion to invite attention to several points in connection with the epidemic occurrence of yellow fever in the United States at the present as well as at other times. In the discussion of the symposium on yellow fever at the meeting of the American Public Health Association in Washington in 1903, I called attention[1] to the necessity during the epidemic season for requiring physicians, in cities where yellow fever is prevailing or likely to prevail, to report promptly to the authorities all cases of fever of any kind coming to their notice. This is necessary in order that there may be no delay in the institution of proper measures to protect the community against extension of the disease if it be yellow fever, for this extension will almost surely take place in the more southern latitudes if the patients are not protected from mosquitoes at the outset. If all cases of undetermined fever were promptly reported and at once protected from mosquitoes[2] it would hardly be possible for the disease to spread if it were yellow fever; on the other hand, where the physician waits for the appearance of black vomit, the golden opportunity passes by, for it has been shown that in practically all cases the disease can not be communicated after the fourth day of the fever. For this reason the diagnosis should be anticipated, and all febrile patients should be immediately protected from mosquitoes until it is shown by actual demonstration that they are not suffering from this disease. Epidemics do not follow every introduction of yellow fever; mosquitoes becoming infected may die before they bite a non-immune, or the patients may happen to be treated in a locality free from *Stegomyia.* A group of cases of yellow fever occurring without black vomit usually receives the designation bilious remittent fever, a diagnosis that should be erased from our text-books. Bilious remittent fever, acute in type and of short duration, appearing in the United States, is yellow fever, and it should be so regarded. Bilious remittent fever was formerly regarded as a type of malarial remittent, but that was before the use of the microscope was found to be necessary for a positive diagnosis of malarial infection. We know now that malarial fever is not a disease of cities, but of outlying districts, while the bilious remittent fever, so called, has been recorded in the cities, in epidemic form, and in such intimate association with yellow fever that by some, the diseases were declared identical, and by others the latter was said to be only a modification of the former. Most interesting and important in this connection is the statement cited by La Roche,[3] in his chapter on bilious remittent fever, that "the morbid appearances revealed on dissection are the same in remittent as in yellow fevers." This statement, however, was not wholly accepted by him, for he calls attention to the bronzed appearance of the liver in certain remittents, a condition that we know results only from malarial pigmentation. Now that we can so easily differentiate malarial remittent and typhoid from yellow fever, the diagnosis is much less difficult, except where yellow fever occurs as a complicating infection.

Our confrères in Havana have demonstrated to us that it is possible to prevent the epidemic occurrence of yellow fever, while occasionally admitting cases of the disease into the heart of a city in which the climatic and other conditions are known to be most favorable for its extension in epidemic form, and in which there are more susceptible persons now than ever before. The method suggested here is in many respects similar to, and is based on, the one adopted during the American occupation of Havana.

Since then it has been sufficiently demonstrated, in 1903 and again in 1905, that under the lax system heretofore and now in vogue, yellow fever can easily secure a firm foothold in certain of the southern states and escape recognition until it has passed almost completely beyond control. On both occasions cited, the outbreak was suppressed or limited only by the intervention of the general government, which, through the energetic action of the U. S. Public Health and Marine-Hospital Service, finally succeeded in checking two epidemics that threatened to become little less than national calamities. Great credit is due to those officials for the success that was attained in spite of the extreme delicacy of the situation and the passive opposition encountered from many quarters.

---

* Read at the Thirty-first annual meeting of the American Public Health Association at Boston, September 25-29, 1905.

[1] Report of the Proceedings of the American Public Health Association, vol. xxix, p. 291.

[2] Since this paper was read, I have been informed by Dr. E. Liceaga, president of the Superior Board of Health of Mexico, that the line of procedure indicated is now being followed in his country.

[3] Yellow Fever, La Roche, Philadelphia, 1855, vol. i, p. 590.

Our experiences in Cuba have shown that for the exclusion and suppression of yellow fever absolute hygienic control is necessary, not only of the people at large, but of the patients as well, and especially of the practicing physicians. The aim of modern medicine is the prevention of disease rather than its cure, and the safety and welfare of the thousands of persons exposed demand that the proper measures be instituted and rigidly enforced. No valid argument can be brought forward to show why the United States should not be kept as free from outbreaks of yellow fever as the city of Havana, its former endemic home has been, during the past four years.

To attain this result the following requirements seem to be essential:

1. Our physicians, or at least those who are in control, must disabuse their minds of the impression that black vomit necessarily occurs in the majority of cases of yellow fever.

2. During the epidemic season, viz., from about May 1 to October 31, and in the epidemic zone, physicians should be required to report to the health authorities, immediately, all cases of fever of any kind that come under their observation, whether among their patients or not, and failure to do so should be made punishable under the law.

3. The board of health should be authorized to appoint, with proper compensation, a commission of three experts, all of whom should be men of high reputation as diagnosticians. It should be the duty of this commission to visit without delay all cases of fever reported to the health authorities, and the onus of diagnosis should rest on the commission and not on the attending physicians. They (the commission) should visit each patient daily until the diagnosis is established or the patient sent to hospital, and they should forward promptly to the health department a written report at each visit. The commission should determine whether or not the patient shall be treated as a possible case of yellow fever, and their decision should be final and obligatory on all concerned.

4. All patients presenting the symptoms of yellow fever, and all cases not diagnosed but remaining under suspicion, should be promptly removed for treatment to a hospital especially located and provided with wire screens and mosquito nets, and the whole or a portion of which has been set apart for that purpose. The yellow fever wards or hospital should be under the direct control of the senior diagnosis commission, and the patients should be treated by physicians appointed only on their recommendation and acting under their direction.

5. In exceptional cases, to be determined by the commission, patients under observation awaiting diagnosis could be treated in their homes beneath mosquito netting, and in rooms properly protected with wire screens, until the nature of the case had been finally settled to the satisfaction of the commission.

The commission and not the attending physician should be held *responsible* for the enforcement of all clinical measures necessary for the protection of the community, and they should be empowered to employ such help as seemed in their judgment to be required. They should also be assisted at times by subcommissions appointed on their recommendation.

Under such a system, conscientiously carried out, the occurrence of an epidemic of yellow fever in any city would become an impossibility. Objection can not be made on the ground of expense if the members of the diagnosis commission are paid only for every visit to a patient; under such an arrangement the cost to the city would be trifling when compared with the losses now sustained by individuals and the whole community through the failure of practicing physicians to recognize and report mild cases of the disease. And herein lies the crucial point. The diagnosis must be anticipated and the proper precautionary measures be taken before the disease has fully declared itself. Diagnoses of malarial remittent, and above all of bilious remittent fever, must not be accepted as conclusive until the presence of malarial or other parasites has been demonstrated to the satisfaction of the members of the diagnosis commission. Attention was called two years ago[4] to the fact that over and over again, since the time of Benjamin Rush, yellow fever has stalked abroad in our cities, unrecognized, under the guise of bilious remittent fever. The time has come when a diagnosis of bilious remittent fever should no longer be accepted, for there is no such disease *per se.* We may have malarial fever complicated with jaundice, but this should not change the diagnosis of malaria any more than an accompanying icterus would change a diagnosis of typhoid fever. Similarly a complication of malaria no longer justifies the diagnosis of typho-malarial fever, and that term has properly been discarded. In numerous instances it is stated in the records of the older epidemics of yellow fever that the disease was preceded by, or began as, a bilious remittent fever, just as in more recent times physicians have believed that typhoid fever began as malarial fever. The conclusion is equally untenable in both cases, and the deduction is obvious that cases of so-called bilious remittent fever must be regarded and treated as cases of yellow fever, unless a satisfactory specific cause for the condition can be demonstrated beyond a doubt. It is proper to mention here that in every one of the twenty-two cases of yellow fever purposely inoculated by the Army Board in Cuba, a diagnosis of bilious remittent fever would have been justified if it had not been known that they were produced from true cases of yellow fever, for, although some of them were severe, black vomit was absent from all.

It may seem unnecessarily severe to require physicians under a penalty, to report all cases of fever coming under their observation, but no other means will attain the desired result, and the enormous interests at stake demand that the methods instituted be thorough and that they be rigidly carried out. The appointment of a board of diagnosis, as has been suggested, will relieve the attending physician from the odium that accompanies a diagnosis of yellow fever in a doubtful case, and the board, fully appreciating the responsibility that rests on them, may be relied on to do their duty. During the discussion on yellow fever before the American Public Health Association at its meeting in Washington two years ago, already referred to in my remarks, which were badly misquoted.[5] I urged the necessity for requiring physicians, under a penalty, to report all cases of fever in order that they might be examined by a board of experts (as was done in Cuba), and treated as cases of yellow fever until the diagnosis was established. Only last month, in a conversation on this subject with a physician from a large city in Texas, he laughingly remarked, "We never report our cases of yellow fever until we have about a dozen of them!"

---

[4] Journal Association of Military Surgeons, 1903 (No. 4), vol. xiii, pp. 193, 199 and 200.

The present epidemic in and about New Orleans only serves to emphasize the necessity for such regulations as are here suggested, and this necessity is further emphasized by the statement in the public press of September 5 that "Inspector Brady attributed the continued spread of the disease to the unwillingness or inability of physicians to diagnose mild cases of yellow fever, and that physicians of standing and ability look for black vomit before making a diagnosis." We have elsewhere[6] cited the occurrence of the same difficulty at Key West in 1889, and we again assert that these physicians may be thoroughly conscientious and able men, but they are baffled by the differences between the aspects of the disease as they actually find it and as they have been taught by the best authorities to expect to find it. It is the manifest duty of local health authorities, therefore, to relieve the physician of the burden of diagnosis and to leave that and the adoption of protective measures to the board of expert diagnosticians.

In this connection I beg to be permitted to call attention to the present situation at Jackson Barracks, a station of two batteries of coast artillery, in New Orleans. By the seventh day of the present month a number of cases of yellow fever had appeared in the neighborhood and seven of them in a block that approached within one hundred feet of the officers' quarters. Still the garrison has not been removed and up to the present time no single case has occurred among them; even should a case or two appear an epidemic is not feared. The reason for this is simply that the medical officers know that it is absolutely within their power to prevent any epidemic extension of the disease; they are constantly on the alert, and all cases of fever are handled in the beginning as though they might be yellow fever.

Again, at Fort McIntosh, in Laredo, Texas, in 1903, there were only five cases of yellow fever in a command of 111 officers and men, while in the town alongside them over 1,000 cases and more than 100 deaths occurred. It was found that the five men who became infected had violated orders by visiting the town at night without wearing the prescribed mosquito head-nets, leather gauntlets and leggings.

If, in the presence of cases of yellow fever among and around them, garrisons of soldiers can be protected from the infection in anything like epidemic form, it necessarily follows that the same measures and the same degree of vigilance will protect a community, provided the physicians do their full duty and they are properly assisted by the authorities. The subject is one involving the lives and interests of thousands of innocent persons, and the secret of success lies in eternal vigilance with the determination to allow no case, however mild and doubtful, to escape the fullest precautions.

TEST TYPES ACCORDING TO THE GEOMETRICAL PROGRESSION OF DR. JOHN GREEN.*

CHARLES H. WILLIAMS, M.D.
BOSTON.

In 1868, Dr. John Green, of St. Louis, wrote as follows:

> The letter proeven of Snellen are deservedly the acknowledged standard for determining the acuteness of vision. They are, however, somewhat imperfect both in plan and in the execution of the smaller letters. The defects in plan consist in the selection of letters which are not so uniform in size and character as is to be desired and still more in the fact that the gradations of size in the successive numbers of the series are not uniform. I have now to propose a new series—bearing the constant ratio of .795 and combining the advantage of regular geometric progression with the *preservation* of all the important numbers of Snellen.

A series of such numbers in Gothic form was published in the transactions of the American Ophthalmological Society for 1868.

Again, at the meeting of the Fourth International Ophthalmological Congress, held in London in 1872, Dr. Green read a paper on "Some Improvements in Test Letters," and presented a series of letters arranged according to the geometric progression, in which a constant ratio of $1 : \sqrt[3]{.5}$ (1 : 0.7937) was adopted. He said:

> This series includes all the most important numbers of Snellen and contains very few fractional quantities. After four years of constant use I *now venture to* recommend this ratio of gradation for general adoption.

So far as I know, these test-types were never placed on the market for general sale. No public recognition was made of the soundness of this gradation until the paper by Dr. E. Javal, of Paris, which was read at the Section of Ophthalmology of the Thirteenth International Congress of Medicine at Paris in 1900. He acknowledged the work of Green in 1868, but recommended a geometric progression on the ratio of 1:1.41, that is the $\sqrt{2}$. He concluded his paper with this sentence:

> En effet je ne doute pas qu'avec le temps, les échelles *a progression géométrique* proposees par Green dès 1868, ne *soient universellement* adoptées.

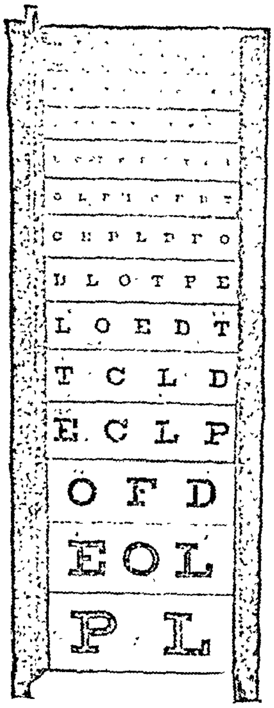
The standard of normal acuteness of vision proposed by Snellen more than forty years ago, and which has been so universally adopted, namely, the ability to recognize isolated capital letters whose height subtends a visual angle of five minutes, and the width of whose component lines subtends an angle of one minute, ought to be retained, but we must remember that when Snellen made his experiments to determine the smallest visual angle at which letters could be recognized by normal eyes, he included in this class all eyes having an error of refraction of less than one diopter. The result is, for normal eyes free from errors of refraction, the visual angle of five minutes is somewhat too large, since these eyes can see letters which subtend a smaller angle than five minutes, and in arranging a new series of test-types at least one line of letters should be provided which subtends less than the five-minute angle. If we start with an accepted testing distance of five meters, it will be best to have the letters of the smallest line of test-types of such a size that at a distance of four meters they will subtend the standard visual angle of five minutes, and if these letters can be read at the five-meter distance they will represent a vision of 5/4 (or 1.25) of the Snellen normal. Taking four meters for our smallest line of test types, equal to V.=5/4 (or 1.25), and fifty meters for the largest line, equal to V. = 5/50 (or 0.1), as representing the extreme range that it is desirable to cover in such a series of test-types, let us construct a series of figures for the intermediate lines according to the proposed ratios of Green and of Javal, and compare them with each other and with the Snellen series.

---

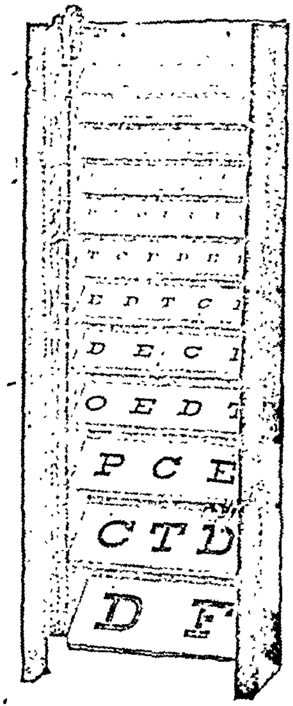
*Read in the Section on Ophthalmology of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

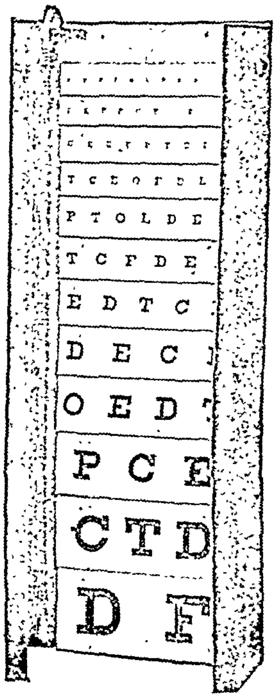
Beginning with 4 (4 meters) and applying the Green ratio for an ascending series of $1:\sqrt[3]{2}$, or 1 : 1.2599 (approximately 1.26), we get the following:

Let 4 = the number for the first line, and x = the number for the next line.
$4 : x = 1 : 1.26.$
$x = 5.04.$
For the next line:
$5 : x = 1 : 1.26.$
$x = 6.30.$
For the next:
$6.3 : x = 1 : 1.26.$
$x = 8.$



C E P L F T O
D L O T P E
L O E D T
T C L D
E C L P
O F D
E O L
P L





It will be found that, beginning with 4, the fourth figure in such a series will be just double the first, and, as this rule applies throughout the series, the numbers are easily found as follows: 4, 5, 6.3, 8, 10, 12.6, 16, 20, 25.2, 32, 40, 50.

Again, if we apply Green's ratio for a descending series of $1:\sqrt[3]{.5} = 1 : 0.7937$ (approximately 0.8), we get:

50 for the first line:
$40 : x = 1 : 0.8 = 40$ for the second line.
$40 : x = 1 : 0.8 = 32$ for the third line.

The fourth line will be one-half of the first, and so on through the series, giving a descending series of 50, 40, 32, 25, 20, 16, 12.5, 10, 8, 6.2, 5, 4, which is practically the same as the first series. The exact figures for such a series, beginning with 4 and taking Green's ratio of 1:1.2599, are as follows: 4, 5.0396, 6.3494, 7.9996, 10.0787, 12.6982, 15.9985, 20.1565, 25.3952, 31.9954, 40.3110, 50.7878, but for practical purposes the approximate series already given is all that is needed, and the difference between the series, approximate and exact, is very small.

Javal's ratio of $1:\sqrt{2} = 1.41$ gives the following series: 4, 5.6, 7.9, 11.2, 15.8, 22.3, 31.4, 44.3, 62.5, In this series of Javal there are not enough lines to get the finer differences needed between the different lines of test-types, especially in the smaller sizes of letters, also there are too many fractions, but this last could be improved by constructing a series with the same ratio, 1.41, but beginning with 3.5 instead of with 4. In this case the approximate series would be 3.5, 5, 7, 10, 14, 20, 28, 39, 55.

Snellen's series is 5, 6, 10, 15, 20, 30, 50. It will be seen that the ratio of Green gives a greater number of lines where most needed and is better adapted to the needs of every-day use, where small differences in acuteness of vision are to be tested.

In the series of test letters here presented, the shape of the Snellen block letter has been retained, only those letters have been used which could be drawn in a square with equal height and width, the height of each letter is five times the width of its different parts, and the height of each letter subtends the Snellen visual angle of five minutes at the distances in meters shown at the left of each line in red numbers. The ratio is the geometrical ratio of Green: $1:\sqrt[3]{2}$ (1:1.26) for the ascending series, and $1:\sqrt[3]{0.5}$ (1:0.8) for the descending series. The letters have been drawn with great care, and the plates have been engraved so that the printed height of the letters will not vary more than 1/100 of an inch from the calculated sizes. On the right hand side of each line is another number in red, giving the acuteness of vision in decimal notation, which will be found convenient by those who have used the Monoyer scale. These decimal numbers are adapted to a testing distance of five meters.

By using the numbers on the left hand of each line the letters can be used at any desired distance, since the ratio between the lines is a constant one and the Snellen formula of V. = d/D applies for each distance. Thus, at a distance of five meters the person who reads the five-meter line will have V. = 5/5, or 5/10 if he reads the third line below it; so at a distance of 4 meters, if a person reads the top line he will have V. = 4/4, or 4/8 if he can only read the third line below it, and so on through the series. The numerator of the fraction being the greatest distance in meters at which the letters are read, and the denominator being the distance in meters at which the letters subtend the visual angle of five minutes, according to the Snellen formula $V. = d/D$.

In the series of letters now presented the reversible feature is new. Each line of letters is printed in duplicate, with a different arrangement of letters on each, these lines are pasted on slats and the slats mounted in a suitable frame so that they all can be rotated by pulling a cord from across the room near the trial case of glasses; in this way the series of letters can be changed at will and a new series used for each eye. The plan of the reversible slats having been found somewhat expensive in its mechanism, a simpler arrangement has been contrived; the same series of lines are pasted on two sides of a long card, the card is then suspended from a simple support that can be rotated either way by a cord from across the room, so that each side of the card can be exposed to view at will.

The different distances in meters at which the letters subtend the visual angle of five minutes, and the heights of the letters on each line, in fractions of an inch are given in the following table as calculated by the formula $X = 2\ AB\ \sin.\ \frac{1}{2}a$ in which X is the desired height of the letter. AB is the distance of the letter from the eye, and a is the visual angle of five minutes.

Distance in meters at which height of letters subtends a visual angle of five minutes.	Height of letters in fractions of an inch.

The reason for giving the heights of letters in fractions of an inch instead of in metrical numbers is that our engravers are not accustomed to work with metrical measurements and errors are less likely if they use the units they are familiar with in preparing the plates. Another feature in connection with the arrangement of test letters on the slats is the constant illumination, which, in a set of test letters used to compare variations in vision from month to month or year to year, is important.

As far back as 1866 Dr. H. Derby of Boston wrote as follows in a paper read before the American Ophthalmological Society for that year: "Let the letters used as a test be placed in a room from which the daylight is excluded, and let them be illuminated by a steady flame, uniform in intensity of illuminating power, and placed always at the same distance from the letters." The letters now presented are illuminated by a series of sixteen eight-candle power incandescent lamps with frosted bulbs, placed on each side of the test letters at equal intervals, eight lamps on each side, and screened from the patient by a tin shield. In this way a very even and clear illumination of the test letters is obtained. The lamps are placed in a vertical row on each side of the letters and 25 cm. in front of the plane of the test card. Each line of letters is engraved on a separate plate, so that they can be arranged and printed with the larger letters at the top or at the bottom of the series as desired.

DISCUSSION.

Dr. Dudley S. Reynolds, Louisville, said that at thirty-five feet he can see the letters in the second line, that would indicate acuity of vision = 8/5. In Snellen's test the basis of the test is the establishment of positive infinity at six meters. A nearer approach than that, Dr. Reynolds thinks, would impair the value of the test. Then, too, this artificial light gives such intense illumination as to change the visual angle; it establishes an unnatural condition. No one has such illumination on the street or to read by, and it seems to him that the scientific value of the test is destroyed by this brilliant lighting.

Dr. G. C. Savage, Nashville, Tenn., said that there are two sets of corneal curves. The refractive curves pass through the center of the cornea. The corneo-retinal curves or meridians may pass through the center of the cornea or may not. If the anterior pole is five degrees to the nasal side of the corneal center, then it is impossible for a perfect focus to be on the macula in that eye. The anterior pole is a point on the cornea cut by the visual axis. The posterior pole is the center of the macula. If the axis cuts the cornea to one side of the corneal center, the best focus must be to one side or the other of the macula. It has saved him time and trouble, before sitting down to refract a patient, to take this into consideration. If the anterior pole corresponds to the center of the corneal curve, the patient will have 20/15 vision, but if the anterior pole is located to one side or other of the corneal curve the patient will not have more than 20/20, or perhaps not that.

Dr. C. H. Williams said that Dr. Reynolds does not seem quite to appreciate the fact that the idea of these test types is to retain the Snellen standard angle of five minutes and his formula. Dr. Reynolds' statement that he can see the letters across the room at a greater distance than six meters demonstrates exactly what these types are intended for, and that is that there are a great number of patients who have a greater acuteness of vision than 6/6 of Snellen's standard, and it is desirable to have a form of types which will retain that standard and at the same time enable the ophthalmologist to measure vision of a little more than the six-sixths of his types. In reply to a question Dr. Williams stated the lights he uses in his office are a little less brilliant perhaps and he is not prepared to advocate such intense illumination, though he thinks it necessary to get at a standard illumination.

Special Article

IMMUNITY.

CHAPTER XXVII—(Continued).

TUBERCULOSIS.

Occurrence Outside the Body.

Dried Sputum.

The tubercle bacillus undergoes no proliferation outside the body and its occurrence in nature depends on the distribution of the *infected excretions*, particularly the sputum, of *man*. Hence it is found most abundantly in the rooms and homes of patients and in tuberculous wards of hospitals. Reception of sputum on the handkerchief of the patient, where it subsequently dries, and its discharge on the floor in public places, where it quickly becomes pulverized, as in street cars, are conditions which favor dissemination *and the infection* of others. In unconfined places which are exposed to the action of light and sun, as the streets and sidewalks, the danger is less on account of the shorter life of the organism under these conditions and the greater volume of surrounding air. The calculation of Heller that a tuberculous *patient* may excrete 7,200,000,000 of bacilli in a day suggests the number which may lurk in a single misplaced portion of sputum. Sputum which is kept moist is *not a source* of particular danger, inasmuch as ordinary *currents* of aid do not dissipate it in the form of infected drops. Droplets of sputum which are expelled by coughing contribute greatly to the infected dust which surrounds a *patient*.

Large *quantities* of bacilli are often excreted in the feces in intestinal tuberculosis *and in* the urine in genitourinary tuberculosis, or in general *miliary* tuberculosis with localization of the process in the urinary organs.

Bovine and Human Tuberculosis.

Great interest attaches to the possibility of infection of man by the milk and meat of tuberculous cattle. Previous to 1901, through the work of Smith and others, the opinion had been gaining ground that the bacilli of human and bovine tuberculosis are not identical. It was not always possible to produce tuberculosis in cattle by feeding them or causing them to inhale tuberculous sputum or pure cultures which were highly infectious for other experiment animals, although bacilli of bovine origin invariably caused the disease in cattle when administered in a similar manner. It seemed then that the two bacilli are not identical in their pathogenic powers. Koch having repeated these experiments without being able to infect cattle with bacilli of human origin, expressed his belief that the converse also is true, i. e., that the bovine bacillus is not pathogenic for man. Perhaps the strongest argument in favor of this view is the circumstance that primary tuberculosis of the intestines and mesenteric glands is very rare in children, who drink a great deal of milk, in spite of the great prevalence of tuberculous cows. Many protests followed the announcement of Koch's views, and in a short time a number of investigators showed, first, that it is possible in some cases to produce tuberculosis in cattle with tuberculous material from man, and, second, that infection of man with the bovine bacillus is possible. Unquestionable proof of the latter consists in the development of localized tuberculosis in those who have performed autopsies on tuberculous cattle (Ravenel and others). These occurrences, of course, do not prove the identity of the two organisms, for there is still abundant reason to believe that the two bacilli are most pathogenic for their respective, natural hosts, and much less pathogenic for the alternative hosts. Theobald Smith has pointed out that many experiments in which the pathogenicity of the human bacillus for cattle was investigated by the feeding of tuberculous sputum, must be repeated, inasmuch as it was not determined in advance whether the organism contained in the sputum was of the human or bovine type. Naturally, absolute conclusions as to the pathogenicity of the human bacillus for cattle could not be drawn with this fact undetermined. In some cases the combined sputum from many patients has been fed to cattle, and since both human and bovine bacilli may have been administered, the results are valueless in relation to the point under discussion. In each instance the organism should be obtained in pure culture, its identity as a human or bovine bacillus determined and the experiment performed with such pure cultures.

Differences in the Bacilli.

The following points serve to distinguish the bovine bacillus from the human: First, the bovine bacillus is shorter than the human; second, when first cultivated it grows feebly in media in which the human bacillus flourishes; third, it has a higher virulence for rabbits and guinea-pigs; and, fourth, it produces more extensive lesions in cattle. To these Smith has added a fifth point, which he has found to be distinctive in a large number of cultures. In bouillon which contains 5 per cent. of glycerin and which is 2 per cent. acid to phenol phthalein the bovine bacillus produces a neutral or faintly alkaline reaction in from three to several weeks, whereas the human bacillus, after causing temporary alkalinity, produces a terminal acidity of from 0.5 to 1.5 per cent. On the basis of this test and other points the bacilli of two cases of mesenteric tuberculosis in man were recognized as bovine in type. In view of the fact that infection of man with the bovine bacillus has been shown to be possible, we are still justified in considering the meat and especially the milk of tuberculous cattle as the probable sources of infection in a limited number of cases.

Congenital Tuberculosis.

Comparatively few cases of undoubted congenital tuberculosis have been observed, and in such cases the mothers are usually in an advanced stage of the disease. It is probable that the organisms reach the fetus following metastatic invasion of the placenta. In a number of cases in which the mother had advanced tuberculosis the organs and blood of the fetus (stillborn or dying soon after birth), contained very many bacilli, although histologic lesions had not as yet been produced. Warthin and Cowie suggest that the tissues of the fetus may possess considerable immunity in such cases. Baumgarten is a strong believer in the possibility that tubercle bacilli may pass to the fetus during pregnancy and, remaining latent in some of the tissues (lymph glands) for a long period, cause active tuberculosis later in life. Others who are less radical still admit that we should consider this as a possibility (Warthin and Cowie, Harbitz).

Infection Atria.

Pulmonary tuberculosis is by far the most common form of the disease in man, and without doubt this is due to inhalation of the dried and pulverized sputum of tuberculous patients. Direct drop infection may well occur in the case of those who are in prolonged and intimate contact with the sick. In kissing direct infection from mouth to mouth is a dangerous possibility.

The reason for the inception of pulmonary tuberculosis in the apex in so many cases is not clearly recognized, although it is often referred to the relative immobility of this tissue, which renders excretion more difficult and affords improper aëration. These conditions not only allow the organisms to accumulate and to proliferate, but the insufficient oxygenation probably causes a low tissue resistance. The suggestion which has been made that apical tuberculosis is the result of extension of the disease from the cervical glands does not correspond with the condition seen in tuberculosis of adults in whom the cervical adenitis is commonly wanting.

The "anatomic tubercle" is a primary infection of the skin; lupus vulgaris, it is supposed, may be either a primary infection or secondary to tuberculosis in some other organ; ulcerative tuberculosis is usually a secondary lesion, often occurring by direct extension from tuberculous lymph glands. Tuberculosis of the nose is uncommon. Infection of the tonsils is not infrequent and probably is a common cause of secondary tuberculosis of the cervical lymph glands. Primary infection of the pharynx sometimes occurs and large, coarse granulations of this surface have been proved in some cases to be of a tuberculous nature. Tuberculosis of the pharynx and larynx, however, most often arises from infection with tuberculous sputum.

In the process of dust infection of the lungs, and also by other means, many organisms lodge on the mucous membranes of the nose, mouth, pharynx, trachea and larger bronchi, but usually without producing a tuberculous infection. The conditions at these points, on account of the movement of the ciliated epithelium, tortuosity of the nasal channels, excretion of the bacilli with mucus are not favorable for infection.

Tuberculous ulcers of the esophagus and stomach are very rare, as is primary tuberculosis of the intestines. Secondary tuberculosis of the intestines is not infrequently caused by the infected sputum which the patient swallows. Primary infection of the genital organs may be caused by direct contact.

That tubercle bacilli have often been found on the hands and finger nails of the sick as well as on those who are intimately associated with them, is a significant fact in relation to the possibility of infection by direct contact.

Lymphatic Metastases.

From a given focus tubercle bacilli extend to other structures in several ways. On more or less theoretical grounds one speaks of "extension by growth" of the organism into contiguous tissues. The commonest method of extension, however, is that of metastasis by way of the lymph channels. When bacilli penetrate a surface, with or without formation of a lesion at the point of entrance, as in the mouth cavity, intestinal canal, or bronchial surface, they are carried to the lymph glands of the region in which the tuberculous process is instituted. As in plague, the infection atrium at times is indicated by the set of glands which is involved. In certain localities the secondary invasion of other structures takes place directly without the intermediate involvement of lymph glands, as in tuberculous meningitis caused by extension from the middle ear, and tuberculous peritonitis or pericarditis by extension from the pleura. Very frequently tuberculosis of the lymph glands and other tissues heals spontaneously, as described below. In case such healing does not occur, metastases eventually continue from one lymph gland to another and to new sets of glands until the larger lymph channels are reached, as a consequence of which extensive regional or general tuberculosis results. Accidental localization of a focus often causes a wide departure from the slow development just described.

Other Channels.

Not infrequently tuberculosis in a lymph gland, which is contiguous to a large lymph channel, as the thoracic duct, invades the wall of the latter, the surface softens from caseation or liquefaction and the contents, impregnated with countless bacilli, are gradually thrown into the circulation. Miliary tuberculosis, first of the lungs and then of other tissues, through the arterial circulation, follows such an accident. A similar course, with variations in localization, follows invasion of the walls of branches of the pulmonary artery or vein. Rupture of a focus into a bronchus is followed by regional or more extensive dissemination of the bacilli throughout the lungs by respiratory forces.

Consolidation.

A slower eccentric extension is seen, particularly in the lungs, in which smaller and larger areas of consolidation occur. By means of short lymphatic metastases into contiguous territory new foci are instituted, which eventually fuse with the original lesion. It is suggested and generally believed that bacilli may be carried longer or shorter distances by wandering phagocytic cells. When tuberculosis once involves a surface like that of the pleura, peritoneum, pericardium or pelvis of the kidney, the whole surface frequently becomes involved in thickly studded miliary tubercles. It is probable that a great deal of dissemination is accomplished by the movements of the fluids and the surfaces of these cavities. In other instances, as in the ureters, Fallopian tubes and spermatic cords, extension seems to occur in the submucous tissue by means of the lymphatics. The autopsy often discloses that tuberculosis which appeared to be "primary" in such organs as bones, suprarenal glands, and meninges was preceded by an old process in a lymph gland from which metastases occurred to the tissues in question.

Certain anatomic conditions produced in tuberculosis which are associated with recovery from the disease, or contrary, may be referred to.

The Tubercle.

The tubercle, the histologic unit of the tuberculous process, is produced as follows, according to the interpretations of Baumgarten: When a bacillus reaches a lymph gland, for example, it multiplies slowly and partly through its presence as a foreign body, but particularly through its toxic secretions, injures the surrounding connective tissue and endothelial cells to a certain degree. Under some circumstances, especially in the parenchymatous organs and lymph glands, this injury may be so great as to cause the death of the adjacent cells (focal necrosis).

"Epithelioid" Cells.

When it is of a lower order the connective tissue and endothelial cells respond to the stimulus by dividing mitotically and eventually accumulate in large numbers within a limited area surrounding the micro-organisms. Not only the endothelial cells of the lymph spaces, but also those of the adjacent blood vessels, take part in the proliferation, many of the vessels being obliterated in consequence. Not infrequently bacilli are ingested by the new cells, although the ability of the latter to destroy the organisms is not clearly established. Metchnikoff says that tubercle bacilli may remain intracellular for many months and although not killed, the pathogenicity is decreased or destroyed. The new cells are of polygonal shape, are fairly rich in cytoplasm, contain large vesicular nuclei and are termed "epithelioid" cells.

Giant Cells.

Certain of the epithelioid cells, usually those in the center of the tubercle, where the bacilli are most numerous, undergo atypical proliferation in that repeated nuclear division takes place without corresponding division of the cytoplasm. This process results in the formation of the multinuclear giant cell which is so characteristic of the well-developed tubercle, although not distinctive of the disease. According to Weigert, the failure of complete cell division is due to injury to the cytoplasm (partial necrosis) by the bacteria which the cell contains. Metchnikoff and others take a different view of the formation of giant cells, considering that they represent individual epithelioid cells which have fused to form a multinuclear mass.[1]

Still more remote from the center of the tubercle, that is, surrounding the epithelioid cells, wandering lymphoid and plasmal cells accumulate.

Retrogressive Changes.

Certain retrogressive changes, especially necrosis and caseation, characterize the further history of the tubercle, although these changes do not occur equally early nor with equal intensity in all cases. Necrosis begins in the center of the lesion, and the view is often expressed that the formation of the giant cell is the first indication of the retrogressive change. Cell degenerations, however, with karyorrhexis may occur before giant cells have formed. With the death of the central tissue there occurs sooner or later the death of many of the bacilli in this portion of the tubercle. The progressive formation of new tissue continues in the periphery as the degenerative changes take place toward the center; the tubercle enlarges, both epithelioid and the surrounding lymphoid cells increase correspondingly, and new giant cells form at the periphery of the necrotic center, only to be included in the degenerated area as the latter extends.

Formation of Fibrous Tissue.

In favorable cases, in which the virulence of the organism is low or the resistance of the individual strong, new connective tissue is formed in the periphery of the tubercle and surrounding it. This new tissue is produced by the maturation of the epithelioid cells, the lymphoid and plasmal cells participating in the process, directly or indirectly. With the further growth of the connective tissue the tuberculous area is eventually surrounded by adult fibrous tissue which in a sense accomplishes the isolation of the infected area. Without question such a capsule of scar tissue is an obstacle to the extension of the tuberculous process, whether it surrounds a nodule in a lymph gland, a cold abscess or a tuberculous sinus.

Caseation, Calcification and Liquefaction.

Further steps in the healing consist of caseation of the entire area, its partial or complete substitution by connective tissue (tuberculous scars), or partial impregnation with lime salts (calcification). Not infrequently the caseous portion of a nodule undergoes liquefaction, which some have referred to the action of proteolytic ferments. The contents of such foci finally become sterile. In the event that healing of this nature does not occur, the infection is transmitted to other organs as described above.

General and Secondary Disturbances.

The temperature, loss of weight, fever, increased cardiac action, and arteriosclerosis which are seen in tuberculosis indicate that the products of the bacillus have a profound effect on the functions of the body, and produce great disturbances in metabolism, although they seem to have no marked selective action for particular tissues. Many disturbances are secondary to changes produced in particular organs and not referable to specific action of the toxins, such as those which are consequent on poor oxygenation in pulmonary tuberculosis, and the amyloid degeneration which follows prolonged suppurative tuberculosis.

Mixed Infections.

Mixed infection, especially with the streptococcus, plays a very important part in the course of pulmonary tuberculosis, especially in the caseous and cavernous forms. Staphylococci, *B. pyocyaneus*, various diplococci, the pneumococcus, bacillus of Friedlander, diphtheria and pseudo-diphtheria bacilli, and the influenza bacillus are also found as secondary organisms in pulmonary tuberculosis. Some of them invade the surrounding healthy tissue, cause lobular consolidations, and in this way probably prepare a favorable soil for further extension of the tuberculous process. They doubtless hasten the liquefaction of caseated tissue, a step in the formation of abscesses. The high and irregular fever often seen in advanced tuberculosis is commonly septic in its cause, and a terminal streptococcus septicemia is not infrequent. It is evident that mixed infections may complicate attempts at serum therapy.

---

[1] A formation analogous to the latter process is seen in the peritoneal cavity of the guinea-pig, in which leucocytes fuse to form a plasmodial mass around yeast cells which are injected.

Clinical Notes

THE METHOD OF GIEMSA FOR STAINING THE SPIROCHÆTA PALLIDA.

LEONARD K. HIRSCHBERG, A.B., M.D.

BALTIMORE.

Under the direction of Professor Charles F. Bevan, of the College of Physicians and Surgeons, considerable study is being given to the *Spirochæta pallida* of Schaudinn and Hoffman. The results of these studies will shortly be published by Professor Bevan and myself. In this search we have been fortunate enough to find *Spirochæta pallida* in the urine of one patient, with active secondary manifestations.

In the meanwhile, since there has as yet been no English or American publication of the stain which has proved so effective in elucidating these organisms, I do not think it out of place or premature to publish Dr. Giemsa's method, somewhat modified from his first description.[1]

GIEMSA'S STAIN.

Azur II—Eosin, 3.00 gms.

Methyl alcohol, 250 c.c.

1. Fix by spreading the specimen very thinly over the cover-slip; dry it in the air.
2. Harden it in absolute alcohol for from 25 to 60 minutes and blot with filter paper.
3. Dilute the stain with distilled water. Pour it into a wide graduated reagent glass by shaking 1 drop of the stain to each c.c. of water out of a drop bottle which first has been rinsed in absolute alcohol.
4. Cover the preparation with the diluted stain for from 10 to 15 minutes.
5. Wash off with running water.
6. Blot with filter paper, dry, and mount in Canada balsam.
7. Overstained specimens may be differentiated in distilled water for from one to five minutes.
8. It is often advisable to make the diluting water alkaline by 1 to 10 drops of a 0.01 per cent. potassium carbonate solution.
9. It is doubtful if staining the *Spirochæta pallida* of Schaudinn for more than one hour will define it any more clearly than staining for that period.

UNTOWARD EFFECT OF ADRENALIN IN THE URETHRA.

W. S. JOHNSON, M.D.,

SAN FRANCISCO.

A patient whom I have been treating for stricture of the urethra, and in whom I have passed sounds for several months, came to my office in his usual good spirits, and in perfect health. After passing a No. 27 French sound, there was some little bleeding from the urethra, which I attempted to check with a solution of adrenalin chlorid, 1-4000, injected in the urethra with an ordinary glass syringe, filling the entire anterior urethra. The following symptoms occurred instantaneously: Lividity or pale lead color of the skin; the eyes set and glassy, the patient crying out, complaining of a bursting sensation in his abdomen, chest, neck and head, saying the top of his head would burst open; a tingling and pressure in hands, arms, legs and feet; vomiting of a projectile character, followed by complete collapse, without loss of consciousness, lasting for a period of ten minutes; respiration shallow, pulse imperceptible and heart sounds inaudible; the patient having the appearance of a case of acute anemia. Restoratives, such as strychnin, 1/20 gr., whisky and aromatic spirits of ammonia were used hypodermically and the patient gradually recovered, but was unable to stand on his feet for three hours. The dizziness lasted until bedtime.

A RETENTIVE APPARATUS FOR FRACTURES OF THE CLAVICLE.

RAYMOND RUSS, M.D.

Instructor in Surgery in the University of California.

SAN FRANCISCO.

In the clinical work at the surgical dispensary of the University of California the Sayre adhesive plaster dressing has been used for some time as a routine treatment for fractures of the clavicle. In many cases the results attained were good, but the method of treatment failed in a number of instances. It was not until several of these failures followed closely on one another that the necessity for a better method of treatment became imperative. The most pronounced failures were in those rare cases of fractured clavicle which presented great overlapping of the fragments and in which it was impossible to maintain reduction by the ordinary methods.

A glance over the literature was not reassuring. More methods of treatment have probably been suggested for this fracture than for any other. Pilcher sums up the matter by saying: "The fact remains that those methods which are efficient are intolerable and those which are tolerable are inefficient." Gurlt makes the statement that there have been about seventy dressings devised for the purpose of drawing the shoulder upward, outward and backward, this being the manipulation for reducing the fracture and maintaining reduction which has been adopted by most authors.

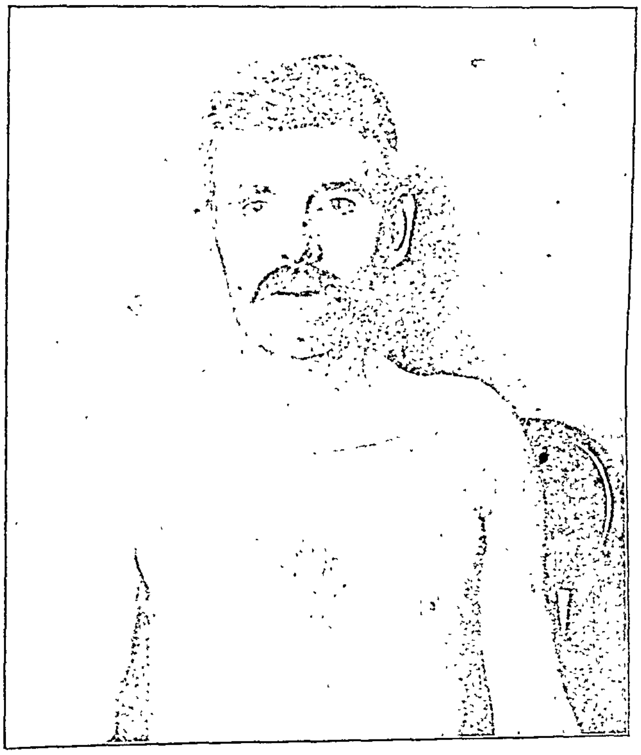

Figure 1.

As the success of methods of detention depends directly on a knowledge of the displacement and the muscular forces which cause it, a consideration of these subjects will not be out of place.

Deformity following fractures of the clavicle is evidently produced by the weight of the shoulder combined with muscular action. This destroys the juxtaposition of the fragments unless impaction has taken place. The serratus magnus and pectoralis minor muscles pull the scapula forward and inward as pointed out by Gordon of Belfast, and by Packard. But the pull of the serratus magnus is probably counteracted to a certain extent by the action of the trapezius. The acromion is thus carried toward the median line and tilted downward, this movement carrying the proximal end of the distal fragment inward so that many times it lies directly below and behind the inner fragment.

This new position of the outer fragment may force the inner fragment somewhat upward, the action being aided by the resiliency of the sternal end of the clavicle and probably by a certain amount of pull by the sterno-cleido-mastoid. The subclavius muscle very possibly aids in the production of the malposition of the outer fragment. The excursion of the scapula, however, is almost immediately checked by the levator anguli scapulæ which exerts a strong pull on the superior angle of the scapula, resulting in an approximation to the spine and a slight prominence of the inferior angle.

---

[1] Deutsche med. Wochft.

It is true that the shoulder changes its position after fracture of the clavicle, falling downward, forward and inward, but it must be borne in mind in the treatment that this deformity can not be corrected in all cases by simply lifting the shoulder upward, backward and outward, as recommended by many authors. Not until the scapulæ are brought well back will the fracture be reduced. This fact has long been recognized. It is commented on by Hippocrates, who suggests that the patient be placed on his back, with a small, hard pillow resting between his shoulders. Guy de Chauliac placed his knee between the patient's shoulders and in this way drew them backward.

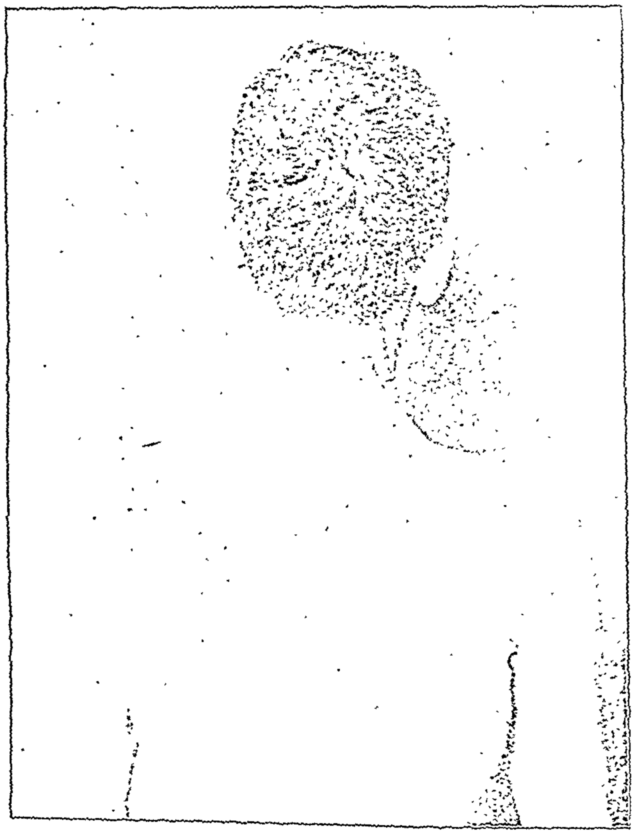

Figure 2.

I have never failed to accomplish reduction, in cases of great overriding, by placing the patient in the position of Hippocrates. Sometimes, however, one must bring the scapula back very forcibly while the patient is lying in this position, and in one of my cases it was found necessary to exert considerable pressure over the point of fracture in order to maintain reduction. This fact has been commented on by Malgaine, who suggested that double hooks, such as he had used in fracture of the patella, might be employed for this purpose. I can find no record of this idea being carried out.

These facts have been emphasized because the underlying principles have been forgotten in many of the dressings which have been proposed. From practical considerations, it would seem that a retentive apparatus should exert firm pressure over the seat of fracture and at the same time should retain the scapulæ in the positions which they assume in the method of Hippocrates.

Plaster-of-paris as a means of maintaining reduction has been used by Davis, O'Connor, Stimson and several others. The following method is designed more especially for those obstinate cases which have been commented on, although it may be adopted as a routine measure. The patient is placed on his back in the position of Hippocrates and, the fracture having been reduced, the limitations of the plaster-of-paris splint are marked on the skin. The dressing should extend a little above and below the clavicles, as shown in Figure 1. It should cover the injured shoulder and should not interfere with free motion of the arm on the uninjured side. The skin is covered with vaselin and a two-inch plaster-of-paris bandage is applied directly, the turns being held down by an assistant so as to secure accurate coaptation, especially about the site of the fractured bone. The bandage can be made to lie smoothly by reversing each turn over the sternum. When a number of layers have been applied a pair of suspenders are incorporated into the dressing. These have previously been prepared by ripping apart the webbing at the point of crossing in the back and cutting away the leather pieces which fasten to the buttons. Each suspender is then slipped through its buckle. There are now two long pieces of suspender webbing, each provided with a buckle at one end. The buckles are thrown over the patient's shoulders, the finished side of the suspender being turned down and the webbing passed under the axillæ. The plaster-of-paris bandage is rapidly turned over the suspenders so as to secure them to the cast, and when enough turns have been taken to make the cast sufficiently strong to resist muscular action, it is finished by rubbing in a little dry plaster. It is then removed and trimmed to the desired shape, the edges being smoothed by rubbing in plaster-of-paris. With the patient in the position of Hippocrates the splint is reapplied, a layer of cotton, several layers of sheet wadding or a thin layer of felt being interposed. It is secured in position by buckling tightly so as to form a figure-of-eight posteriorly (Fig. 2). It is essential that the dressing be applied tight enough to resist muscular action. The arm on the injured side is then supported by applying a figure-of-eight cravat as shown in Figure 3.

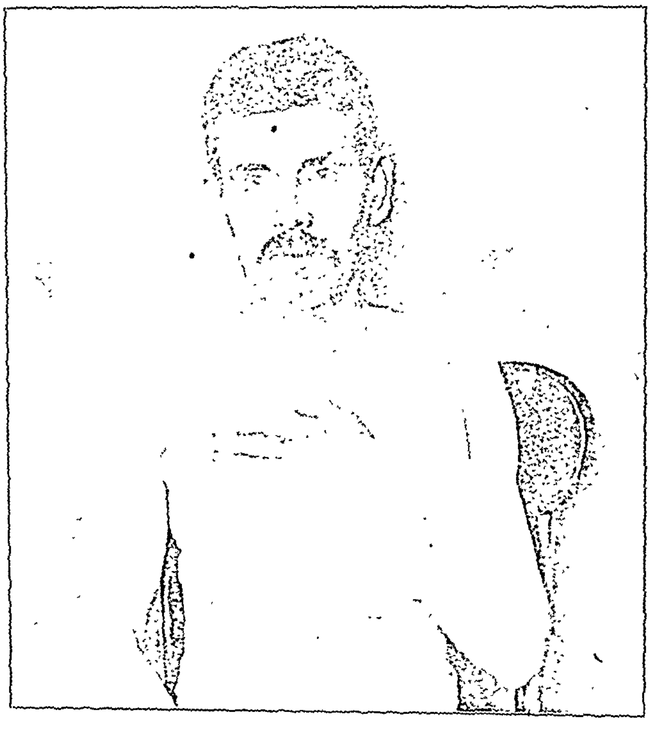

Figure 3.

In certain selected cases the time of functional disability may be greatly shortened by employing a modification of this splint. For this purpose the plaster-of-paris should well clear the injured shoulder. The patient may be given free use of the injured arm after a few days' time. It is evident that if this be done slight movement at the seat of fracture will occur, no matter how tight the apparatus be made. In those patients who do not object to a slight callus deformity and in whom disability is a great hardship, I deem it a proper procedure.

SATURDAY, OCTOBER 7, 1905.

HEMOPTYSIS AND THE PNEUMOCOCCUS.

An interesting point in regard to pulmonary hemorrhage which has been known for many years but has not received the attention it deserves is the fact that when patients suffering from tuberculosis are collected together, and pulmonary hemorrhage occurs in one, it is almost certain to be noted in other patients during the course of the next week. As a rule, this association of symptoms has been considered to be due either to coincidence or to the psychic effect of an event like this on susceptible patients. Usually the subject is dismissed thus without more ado. The older practitioners of medicine frequently referred to this association of pulmonary hemorrhages and attributed it to atmospheric conditions. It was not long ago, however, that most disease changes were attributed to variations in meteorologic conditions, but the tendency recently has been to get away from the supposed effects of the atmosphere on patients, except for minor changes in the sufferer's condition. One striking bit of evidence that impaired the value of atmospheric changes as a reason for pulmonary hemorrhage was the observation that the admission of a patient suffering from pulmonary hemorrhage into a ward containing other patients who had not recently suffered from this symptom, was so frequently followed by the occurrence of hemoptysis in one or two others as to make the event more than a coincidence.

This subject of the concurrence of pulmonary hemorrhage in patients closely associated with one another, has recently been investigated by the Phipps Institute, of Philadelphia, for the study and treatment of tuberculosis, with very practical results. In a preliminary report[1] it is noted that in the ejected blood of a number of cases of pulmonary hemorrhage pneumococci in large numbers were found. The reason for investigating as to the presence or absence of this micro-organism was the fact that even in normally healthy individuals who contract pneumonia, there is a well-known tendency for exudation of blood from the pulmonary vessels manifested by the characteristic rusty sputum of the disease. In four cases of pulmonary hemorrhage carefully investigated the presence of pneumococci seemed to point to some definite etiologic relation between the presence of this micro-organism and the special symptoms noted in the cases.

In two of the cases, there was a history of exposure to pneumonia, and in one a history of contact with a just previously hemorrhagic patient. In three of the cases, pneumococci were found in the blood from the patient. Streptococci were associated with the pneumococci, but there was a definite preponderance of the latter, and in some of the cases it was found in practically pure culture. Only four cases were investigated so completely as to make them available for absolute conclusions, but observations made in other cases point to the same conclusion, that the pneumococcus, if it does not play the only rôle, at least plays a very important one in the production of pulmonary hemorrhage, even during the progress of what seems to be an ordinary case of pulmonary tuberculosis.

All this investigation is, as the authors, Drs. Flick, Ravenell and Erwin, state, of great suggestive value. It opens up one of the most practically interesting fields for investigation that has presented itself in recent years. The New York City committee, investigating the present prevalence of pneumonia, stated as one of its conclusions, that pneumonia was probably contagious to a limited degree and that proper precautions should be taken, therefore, to prevent its spread. This Philadelphia investigation seems to point out one of the most important phases of pneumonia contagion, and suggests also the necessity for careful prophylaxis, especially with regard to patients whose lungs have been rendered susceptible by the presence of active pulmonary tuberculosis. The question of considering pulmonary hemorrhage itself as a manifestation of pneumonia, and consequently of insisting on definite precautions against the possibility of other patients suffering from pulmonary tuberculosis, coming in contact in any way with such patients directly or indirectly, commends itself as an advisable precaution. If this should put an end to what has been considered the curious coincidence of pulmonary hemorrhage occurring in associated patients about the same time, we should have the explanation of a very interesting problem in medicine, and at the same time have made a very distinct advance in the investigation of the occurrence of one of the most serious symptoms that disturb the progress toward health of sufferers from pulmonary tuberculosis.

DIGESTION LEUCOCYTOSIS AND CANCER OF THE STOMACH.

The observation that the leucocytes in the circulating blood are increased after eating is an old one. First noted by Nasse in the middle of last century, the observation was then incapable of rigorous scientific proof, but was finally subjected to accurate tests by Limbeck in 1890. Since then numerous hematologists have convinced themselves that a digestion leucocytosis occurs, though there have been doubters who claimed that the varying counts at different times of the day are due to a normal fluctuation independent of the consumption of food. It was natural that some attempt should be made to apply this observation in the physiology of the blood to the study of the pathology of digestion. It was fair to assume that lesions of the stomach might be followed by changes in this digestive leucocytosis, and Muller, in 1890, was the first to announce that this was the case. His observation, that in cancer of the stomach the normal digestion leucocytosis is lacking, has been investigated by numerous observers and, in the main, has been upheld. Vanstenberghe and Breton,[1] in connection with an investigation of their own, have collected the published results on the subject, showing that of one hundred and sixty-three cases of carcinoma of the stomach a digestion leucocytosis was present in only twenty-nine. Their observations support the view that a distinct digestion leucocytosis exists, reaches its acme about two hours after the first meal, and is independent of the normal variation of the leucocytes at different times of the day.

---

[1] Med. News, New York, Sept. 9, 1905, p. 492; abstracted in The Journal, Sept. 23, 1905, p. 944.

The value of digestion leucocytosis in the diagnosis of carcinoma of the stomach has been differently stated by different observers. Some have stated that it is of no value, but a glance at the table of Vanstenberghe and Breton shows that this opinion has been based on altogether too small a number of cases—two in the case of Hassmann, three in the case of Burian and Schürr. Where large numbers of cases have been observed, the conclusion reached has generally been that the test is at least of confirmatory value. In the largest series of cases reported, those of Cabot and Capps, thirty-four out of thirty-seven cases showed the absence of a digestion leucocytosis. The twenty-two cases of Osler and McCrae, however, showed absence of digestion leucocytosis in only a little over one-half. Control tests of the leucocytosis in new growths of neighboring organs, as the liver and pancreas, show that in these cases also there may be an absence of the digestion leucocytosis. New growths of distant organs, as the uterus and intestine, do not cause an absence of the digestive leucocytosis, nor do other gastric disturbances, such as ulcer. Vanstenberghe and Breton have shown that there is a difference in the character of the digestion leucocytosis as compared with that due to the normal daily range. In the digestion leucocytosis it is the mononuclear elements which are relatively increased, while in the normal daily range it is the polynuclears which fluctuate.

The conclusion which is to be drawn from these observations seems obvious. The figures collected by Vanstenberghe and Breton are large enough to show that carcinoma of the stomach has a decided effect on the digestion leucocytosis in a great majority of cases. The sign is, of course, not a pathognomonic one, but must be of value nearly as frequently as the examination of the stomach juice. It seems as if it must be of considerable use as confirmatory evidence in a great many cases, and on this account, as well as on account of its simplicity, it should be used more extensively than it has been.

ASEPSIS BEFORE BATTLE.

Surgeon-General Suzuki of the Japanese Navy, in his address last week before the Fourteenth Annual Association of Military Surgeons of the United States told of two customs that were introduced into the Japanese navy during the recent war, which were of extreme interest and likely to be far-reaching in their influence, because they are simple and, as a rule, possible. It is no wonder that a distinguished medical authority in the United States Navy is reported to have said in comment that the Japanese surgeon-general had made perhaps the most valuable contribution of modern times to naval surgery. The suggestions that were carried into effect under his directions, however, are so obvious that it is rather difficult to understand how they did not occur to martial surgeons before this. Although the suddenness of the attack would often prevent their use in land engagements, naval combatants usually have sufficient warning of a battle to allow at least a brief preparation. Dr. Suzuki considers that much of the Japanese success in the treatment of wounds must be ascribed to the order issued before every engagement, that each member of the crew should take a bath and put on perfectly clean underclothing.

His idea is that gunshot wounds are likely to be contaminated by portions of clothing carried into the wounds. The bullet itself may be considered perfectly sterile because of the high temperature to which it has been exposed, and which has continued during its course through the air, thus making it practically impossible for it to collect any virulent germs from the atmosphere. If then the clothing be reasonably sterile, the hope of a sterile wound resulting is greatly increased. As a matter of fact, very few of the sailors and marines wounded during the Japanese naval battles and sieges suffered from septic complications. Very severe wounds, even those which penetrated joints, healed as kindly, as a rule, as those which might be made by the surgeon's knife, under the most careful aseptic precautions in an operating room.

A corresponding set of aseptic precautions was long since adopted by French duelists and has saved many a peppery Frenchman from septic complications that might have resulted under other conditions even from slight wounds. This, however, is not the only improvement worthy of note in the medical care of their sailors and marines that the Japanese surgeon-general has introduced. He considers that the vision of the men who aim the guns on a warship must be of the very best if their shots are to reach the target. Before every engagement, therefore, the naval surgeons carefully examined the eyes of all the gunners. Even the slightest impairment of vision was considered sufficient to require prompt treatment and if the treatment was not likely to improve vision in a few days, substitutes were selected to fill the places of the ailing ones. During naval engagements, the crew of every battery was furnished with a 1 per cent. solution of boracic acid, with which the men were instructed to wash out their eyes should they become affected by powder, smoke or dust or dirt of any kind, or be irritated for any other reason.

---

[1] Arch. de Méd. Expér., 1905, xvii, 471.

There is no doubt that the Japanese military and naval surgeons have been extremely ingenious in inventing methods of preventing complications of all kinds. Their application of the asepsis of the French duelists to the many combatants of a naval engagement is a triumph of enterprising application of simple knowledge that stamps them as much more than the mere imitators they are sometimes said to be, and sets them in the rank of the most progressive of modern nations.

YELLOW FEVER.

There is now indisputable evidence that the epidemic is well under control. In New Orleans the improvement has been marked. During the entire week ending October 1, only 193 new cases were reported, with 24 deaths. In Louisiana, outside of New Orleans, not over 150 new cases were reported in the same period. The infected points in Mississippi reported an equal number, and Pensacola 75. Scientific methods have won at every point where they have been thoroughly applied. At Vicksburg and Pensacola the populace is more or less hostile, due to the active opposition of men who should know better. Right-thinking men are astonished at the spectacle of substantial men, in time of crises, actively opposing the efforts of science to conserve human life. All during the epidemic the town of Harriston, Miss., has had an absolute non-intercourse quarantine—so-called—not admitting either freight or passengers, yet it recently has had two cases of yellow fever. It has been demonstrated that there need never again be another epidemic of yellow fever if the first cases are promptly discovered, honestly reported and carefully screened.

SOCIETY CONVERSAZIONE.

At a recent meeting the Pennsylvania State Medical Society introduced what it announced as a new departure, familiar enough at medical conventions in England, but not often attempted in this country, and perhaps never before at a state medical society meeting. In addition to the refreshments and music by a full orchestra, at a general reception given to members, a series of popular addresses was announced for later in the evening. While the younger members of the society and their friends might enjoy the dancing and the music, the more serious-minded attendants at the function had the opportunity to hear various authorities speak on scientific subjects that are of special interest at the present time. Dr. Kellicott, of Columbia, New York, for instance, talked on mimicry and protective coloration, with illustrations of this ever-interesting subject. Mr. Kelsey, of Philadelphia, the well-known architect and landscape gardener and the designer of the model city at the St. Louis Fair, delivered an illustrated lecture on methods of beautifying cities. There was a *demonstration* of radium and of the mercury-tube light invented by Mr. Cooper Hewitt, of New York. Besides this, there were less special features, as a lecture on travel by a well-known popular lecturer, a presentation of methods of mining by means of stereopticon views, special attention being given to the process of anthracite coal mining and the dangers involved in them. Dr. Hollister's collection of Indian relics of various kinds, one of the most noteworthy collections in the country, was on exhibition, as well as Dr. Everhart's collection of native woods and other interesting specimens. No little anxiety to the members of the committee of arrangements is often caused in their endeavors to fill up an evening. This is certainly an interesting way and it is worth considering by other state societies. Under the busy conditions in which they live, physicians seldom have the time to keep abreast of recent scientific developments, though they may desire very much to do so.

FIRST AID IN RAILROAD ACCIDENTS.

In view of the great and rapidly increasing number of fatal and disabling railroad accidents the proposal by certain railroads to drill their train crews in first aid instruction and to establish frequent small hospitals along its line is worthy of commendation. If accidents must happen, and some of them are probably unavoidable, it is really criminal to leave them unprovided for. That a great many more occur than should, makes the need a still more urgent one. It might not be policy to advertise hospital advantages with excursion rates, but to have first aid and hospitals at hand when needed would be one of the best things possible—next to preventing the accidents.

THE PURE FOOD QUESTION.

While Congress is inexcusably dilatory in legislation, Uncle Sam himself in his personal transactions is wide awake as to the importance of pure foods. Adulterated sausages were recently found among the supplies at one of our navy yards and the seller has been arrested and put under bonds, and the matter is to be brought before the federal prosecuting authorities. While there is said to be no federal special statute against selling adulterated food to the government, it is thought that the general law against fraud of any kind will cover the case. It is a pity that corrupt commercialism can avoid penalties under such laws for the public generally, but such seems to be the case. If the medical profession will do its duty and use all its influence we do not believe that the enactment of a federal pure food law can be long prevented. We trust that our leaders will look up the records of their senators and congressmen and act when opportunity offers to insure so far as possible the election of those who are on the right side in this matter.

AN INTERESTING STUDY OF TYPHOID.

It is to be hoped that the outbreaks of typhoid fever, which occur from time to time in various localities and which are usually carefully analyzed in relation to cause, are making a strong impression on the public. The infection is usually due to carelessness—often in either water or milk supply. An instructive report[1] of a study of the Palo Alto epidemic is just received; the milk was at fault in this case. Of the total 236 cases in the epidemic, 216 used milk supplied by one dairyman; 16 others may have been secondary infection, although they used milk supplied by the same milkman; 2 cases were infected while away, and only 2 cases occurred without known connection with the objectionable milk or with previous cases. The portion of the pamphlet by Dr. W. F. Snow on the source of infection in the milk supply shows careful analysis and contains an interesting topographic diagram on which is marked all the movements of milk and of those involved in its contamination. The pamphlet is published as a public document by the Palo Alto Board of Health and the facts brought out—particularly the diagrams—ought to be effective for good.

"SCIENTIFIC WORK MISREPRESENTED AND COMMERCIALIZED."

Two weeks ago we published in our Pharmacology department an exposé of the manner in which the M. J. Breitenbach Company, for advertising purposes, had made an abstract of the official report of the Porto Rico Anemia Commission and had totally misrepresented the conclusions reached by the commission in regard to the value of a preparation which the Breitenbach Company are selling, called "pepto-mangan (Gude)." This week we publish an official statement from the Porto Rico Anemia Commission, which corroborates the statement we made two weeks ago, except in unimportant particulars. There is one sentence in the letter from members of the commission which is worth noting: Speaking of the fact that had they found the peptomanganates of superior value as blood regenerators they would have said so, they add: "As it is, we have said the contrary and wrote this company to that effect at the time we became convinced of it." If the Breitenbach Company received this letter, then they must have deliberately, not ignorantly, misrepresented the commissioners' report.

MEDICAL ADVICE IN LAY PAPERS.

It is a pleasure to note an exception to the questionable character of the departments which appear in various lay publications giving advice on medical subjects. One that has just come to our notice[2] is worthy of commendation—if the initial number is a criterion of what is to follow. In introducing the department the editor remarks that, unless he is mistaken, "there are thousands of things which the people ought to know, which the strictest ethics of the medical profession will approve. . . . We are not among those who think that the medical fraternity is composed of men and women who are entirely mercenary, and while we do not desire or expect them to teach us how to do without a doctor, we do believe, as a rule, that they are ready to co-operate with us in things connected with our every-day life essentially affecting our health and well-being." The physician chosen as editor of the department says that he proposes to conduct the department strictly on ethical lines and makes the following most appropriate quotation from the Principles of Ethics:[2] It is the duty of physicians who are frequent witnesses of the great wrongs committed by charlatans and of the injury to health and even destruction of life caused by the use of their treatment, to enlighten the public on these subjects and to make known the injuries sustained by the unwary from the services and pretensions of artful impostors." He therefore gives the following good advice: "Choose your physician instead of letting him choose you" (by making a display in the community to attract attention). "He should, first of all, be a Christian gentleman. He should be a graduate of an accredited medical school, and if he should happen to have a college degree, all the better, as that is some evidence that he has had additional mental training. He should be temperate; God pity the man, woman or child who has to submit to the ministrations of a doctor whose brain is clouded by liquor or narcotics. . . . We have had considerable to say about doctors, now a word about their remedies. That the American people have become a nation of drug guzzlers is, alas, too true, and a fact greatly to be deplored. The daily press is not without sin in regard to the habits of self-drugging by the people. They recommend—at so much per line—the use of this or that drug without knowing themselves the possible evil effects which may be produced. The public ought to be impressed with the fact 'that drugs are tools by which the physician accomplishes a given end; and, like all other experts' tools, should be handled by experts.'" This and much more on the same subjects. The physician in charge has laid a good series of premises and we shall expect to see more solid sense in future issues.

THE DIRTY RESTAURANT KITCHEN.

It is commonly said that every man must eat his peck of dirt. If the truth were known, this might be found a very mild statement. Some of us are unconsciously habitual dirt eaters. If we could inspect the places where our food is prepared, many of us would require powerful appetites to meet the occasion. This is particularly true of those who have to depend more or less on public eating places. While there are undoubtedly clean restaurant kitchens, there are a very great many more that are far from meeting the simplest requirements of tidiness and sanitation. Of course, the most comfortable thing to do is to eat what is set before one and ask no questions, but the possibilities for reform should not be neglected. The suggestion that municipal authorities inspect and enforce proper cleanliness and sanitary requirements in public restaurants is well worthy of attention. Moreover, the reform ought to be easy. If it were known which restaurants are worthy of public patronage in this respect, they would be likely to get it to the disadvantage of those that are not. There is a wide field for reform here not only in the methods and material outfit of these establishments, but also in their personnel.

[2] The Principles of Medical Ethics of the American Medical Association, Chap. III, Sec. 4.

THE HARVEY SOCIETY.

The Harvey Society of New York is described in its constitution as "a society for the diffusion of the knowledge of the medical sciences." The particular object, judging from the program of its first course of lectures, appears to be to bring the results of investigations in the medical sciences directly to those engaged in the practice of medicine as well as to others. The lectures are given under the auspices of the New York Academy of Medicine. The program[1] of the course for 1905-6 includes lectures by Professor Hans Meyer on "Die Theorie der Narcose;" Professor Carl von Noorden, "Modern Problems in Metabolism;" Professor F. G. Novy, "Trypanosomes;" Dr. R. A. Levene, "Autolysis;" Professor W. H. Park, "A Critical Study of Serum Therapy;" Professor L. F. Barker, "The Neurones;" Professor F. S. Lee, "Fatigue;" Professor L. B. Mendel, "The Formation of Uric Acid;" Professor T. H. Morgan, "Regeneration in Man and Other Vertebrates;" Professor C. S. Minot, "The Nature and Cause of Old Age;" Professor J. C. Webster, "Modern Views Regarding Placentation;" Professor Theobald Smith, "Some Phases of Tuberculosis," and Professor W. H. Howell, "The Cause of the Heart Beat." This is certainly a distinguished company, and the Harvey Society is congratulated on the solid attractiveness of its first annual program. It was a happy idea to establish a society of this kind and purpose. It means a new agency for the popularization, especially among the medical men of New York city, of the results of scientific investigation in various fields of medical and also general interest. Perhaps other medical centers may find it advantageous to establish somewhat similar means for the same general purpose.

---

Physicians' Fees.—There is, it seems to me, one just plan by which fees should be regulated. It is that the physician should have an estimate of the value of his services, operative or otherwise, fixed in his mind. The amount should be based on his experience and skill. It should not be so low as to coax away unjustly the patients of the younger and less experienced men of the profession. This fee should be lessened when the financial position of the *patient* would *make its* payment a serious burden. A well-to-do patient should pay the full fee, which should be generous in order to recompense the physician for his expensive education and hazardous life. [illegible] er, should not be increased because the serv- [illegible] y [illegible] are utilized by a very wealthy person, [illegible] cts [illegible] e is given to the service or an additional [illegible] on the physician by reason of the [illegible] Dr. K[illegible] Roberts. Medical News

GEORGIA.

Changes in Atlanta College Faculties.—Dr. William S. Elkin has been elected dean of the Atlanta College of Physicians and Surgeons, to succeed Dr. William S. Kendrick, and Dr. Stephen T. Barnett, registrar; Dr. James B. Baird has been appointed professor of principles and practice of medicine; Dr. Charles G. Giddings, professor of clinical medicine; Dr. E. Bates Block, professor of clinical medicine, and Dr. Cyrus W. Strickler, associate professor of principles and practice of medicine. The faculty proposes to erect a new building to cost $75,000, of which $30,000 has already been subscribed.

New Medical School.—The Atlanta School of Medicine opened October 3 in its temporary quarters in the Masons' *Annuity Building* with the following faculty: Dr. Howard J. Williams, Macon, special lecturer on surgery; Dr. William S. Kendrick, professor of medicine; Dr. Charles D. Hurt, professor of therapeutics; Dr. George H. Noble, professor of abdominal surgery and clinical gynecology, dean of the faculty; Dr. James M. Crawford, professor of diseases of the eye, ear, nose and throat; Dr. Edward C. Davis, professor of gynecology and obstetrics; Dr. Luther C. Fischer, professor of anatomy and clinical surgery; Dr. Edward G. Jones, professor of gynecology and obstetrics, proctor of the faculty; Dr. Frank K. Boland, professor of operative and clinical surgery and demonstrator of anatomy; Dr. Hansell Crenshaw, professor of materia medica and chemistry; Dr. Stewart R. Roberts, professor of physiology; Dr. James L. Campbell, professor of surgical anatomy and clinical surgery; Dr. William L. Champion, clinical professor of genitourinary diseases; Dr. Robert B. Ridley, Jr., clinical professor of diseases of the eye, ear, nose and throat; Dr. L. Benjamin Clarke, lecturer on diseases of children, and Dr. James H. Crawford, assistant to chair of diseases of the eye, ear, nose and throat.

IDAHO.

State Society Meets.—The Idaho State Medical Society held its annual meeting in Boise, October 5 and 6, under the presidency of Dr. Robert L. Nourse, Hailey.

Personal.—Dr. Adolph Blitz, Boise, who has been ill at St. Luke's Hospital with erysipelas, has recovered.——Dr. John H. Messner, Lewiston, has been extradited to the state of Washington, where he has been charged with arson.

Decides Against State Board.—The Supreme Court has decided that the refusal of the Board of Medical Examiners to grant a license to Dr. J. B. Cooper, Blackfoot, was illegal, as the applicant was legally engaged in the practice of medicine and surgery under the law of 1887, and in accordance with this decision Dr. Cooper was given a license.

ILLINOIS.

Diphtheria Epidemic.—An epidemic of diphtheria is reported to have broken out at Carpentersville, Kane County.

Examination Postponed.—The examination of candidates for the Cook County Hospital staff, which was to have been held September 27, has been postponed.

Donates Hospital Site.—Dr. John W. Tope, Oak Park, has agreed to purchase a site for the proposed Oak Park Hospital, consisting of six acres in Fair Oaks, in the northern part of the village.

Doctors Ill.—Dr. J. H. Porter, Clinton, has gone to Chicago to be operated on for cholelithiasis.——Dr. Lorenzo A. Snyder, Chicago Heights, is critically ill in a Chicago hospital from appendicitis.

Maternity for Evanston Hospital.—A maternity hospital adjoining the Evanston Hospital is to be built as a memorial for the late Mrs. Elizabeth Williams, whose six children have contributed $25,000 to the building fund.

Rattlesnakes as Security.—"Dr." White Eagle, an Indian itinerant, who was recently fined $100 in Blandinsville for illeg [illegible] ne, left a box of rattlesnakes with the [illegible] and has disappeared.

Family Blamed for Death.—In the case of the late Hartford Wiltse, Momence, who died from typhoid fever, the mother and sisters of the deceased, who are "eddyists," were censured by the coroner's jury, whose verdict declared that the man came to his death from typhoid fever and that the evidence showed lack of proper attention.

Antitoxin Agents Appointed.—The secretary of the State Board of Health has appointed antitoxin agents in various counties of the state under the provision of the new law.

The duties of these agents are to distribute antitoxin certified by the State Board of Health to the poor on order of the supervisor, to be paid for by the county, and to sell to those who apply at a fair price.

The Work of the Coroner.—During September 36 more deaths were reported to the coroner than for the preceding month. The total number of deaths requiring investigation was 330. Of this number 40 were suicides, 38 of whom were white and 2 negroes; 31 were men and 9 women, one being a schoolgirl 15 years old; 21 left wives or husbands, 10 were unmarried, 4 were widowers, 1 was a widow and 3 were divorced. The pistol was the favorite means of suicide and carbolic acid held the first place among the poisons employed.

Chicago.

No Smallpox.—For the first time in fourteen years the Isolation Hospital was without a smallpox patient September 26.

Buys Land for Hospital.—Max Eichberg has purchased the building and ground at 3040 Calumet Avenue for $40,000 and will turn it over to the Calumet Hospital.

Asks for More Inspectors.—The commissioner of health has asked the finance committee of the City Council for an appropriation of $8,000 so that he may add six food inspectors and six sanitary inspectors to his present force.

Hospital Reorganized.—St. Ann's Hospital, formerly limited to the treatment of tuberculosis, has been reorganized as a general hospital and a new medical staff has been appointed consisting of Drs. Helga Ruud, John T. Milnamow, Charles E. Humiston, John J. Meany, B. Mack, Fred L. Glenn and Gustavus P. Head.

The Policlinic Transferred.—The Chicago Policlinic Hospital has transferred its property to the Chicago Policlinic for a consideration of $61,000. The latter organization is preparing to erect its new hospital at Oak Street and La Salle Avenue and has obtained a building loan of $300,000 through its president, Dr. Fernand Henrotin, for this purpose.

September Mortality.—The deaths from all causes for September were 2,101, equivalent to an annual rate of 12.78 per 1,000. This is the lowest, with one exception, on record, and the average rate for the decade was 13.95 per 1,000. Acute intestinal disease still heads the list with 451 deaths, followed by consumption with 219, violence including suicide with 180, heart diseases with 163, nephritis with 144, and pneumonia with 122.

Deaths of the Week.—During the week ended September 30, 481 deaths occurred, equivalent to an annual death rate of 12.54 per 1,000. This compares favorably with the death rate of the corresponding week of the previous year, 12.61, and with that of the previous week, 13.40. Acute intestinal disease still holds the lead in death causes with 75, followed by consumption with 57, violence including suicide with 37, heart diseases with 35, nephritis and pneumonia, each with 34, and cancer with 28.

INDIANA.

Health Officers Resigned.—Owing to dissension with the city council, the Board of Health of Columbus, composed of Drs. Richard E. Holder, W. D. Treadway and J. R. Dunlop, has resigned.

Consolidation of Medical Colleges.—Formal announcement has been made of the consolidation of the Central College of Physicians and Surgeons, Indianapolis, with the Indiana Medical College of the same city, and of the incorporation of the two schools as an integral part of Purdue University.——It is reported that the directors of the Fort Wayne College of Medicine will meet in a few days for the purpose of discussing the advisability of merging that institution with the medical department of Purdue University.

IOWA.

College Opens.—The Sioux City College of Medicine opened for its annual session September 19. Dr. George S. Browning delivered the address. Dr. E. A. Jenkinson has been elected professor of embryology, Dr. George S. Browning professor of electro-therapeutics, Dr. Isaac E. Nervig instructor in anatomy, and Dr. E. Ruel Wheeler assistant to the chair of physiology.

Railway Surgeons' Meeting.—At the annual meeting of the State Association of Railway Surgeons, Des Moines, September 21-23, Dr. William Van Werden, Des Moines, was elected president; Dr. Smith A. Spillman, Ottumwa, vice-president; Dr. Albert B. Deering, Boone, secretary (re-elected), and Dr. E. C. McMeel, Delmar, treasurer (re-elected). The next meeting will be held in Des Moines.

Personal.—Dr. John N. Warren, Sioux City, returned from Europe September 27.——Dr. Albert P. Johnson, Sigourney, who was injured several days ago at Rock Island, Ill., in a railroad wreck, is now convalescent.——Dr. Kurt Jaenecke, Clinton, has sailed for Europe.——Dr. Willis W. Dean, Sioux City, left September 20 for the state of Washington.——Dr. Walter A. Sternberg has been elected city physician of Mount Pleasant, vice Dr. John Elliott, resigned. ——Dr. John F. Harp, Prairie City, has been reappointed local surgeon for the Des Moines Valley Railway.——Dr. Maxwell E. Silver, Sioux City, has located in Detroit, and is demonstrator of anatomy and lecturer of osteology in the Michigan College of Medicine and Surgery.

MARYLAND.

Ravages of Typhoid.—A family in Caroline County (Eastern Shore), has been attacked with a virulent form of typhoid fever. The father, mother, two daughters and a son are dead; another son is in the hospital, while two daughters and one son are convalescing.

Diphtheria at Naval Academy.—Owing to the prevalence of diphtheria among members of the new fourth class at Annapolis, the opening of the United States Naval Academy has been postponed until October 7. Meanwhile Bancroft Hall will be thoroughly fumigated. Members of the fourth class are forbidden to leave the limits of the academy. The first, second and third year classes are now on vacation. The members of the football team have returned and are domiciled in Carvel Hall Hotel. There are nine midshipmen affected, and about a dozen others have shown symptoms and are under observation. None of the patients is in a dangerous condition.

Baltimore.

The First Appeal.—The first appeal for aid to the fund for the relief of widows and orphans of deceased physicians was made last week by a physician's widow, aged 70, without support.

Much Tuberculosis.—The reports of the health commissioner show three times as many cases of consumption reported as last year. Consumption caused 29 of the 197 deaths in Baltimore last week.

Physician Wins Suit.—In the case of Dr. J. William Funck, in which damages of $10,000 were claimed for alleged unskillful treatment of fracture of the wrist, a verdict was rendered for the defendant September 27.

Naval Secretary as Auctioneer.—Hon. Charles J. Bonaparte, Secretary of the Navy, announces that he will act as auctioneer at the sale of autographed books to be held in November by the Quarter Club for the benefit of the Hospital for Consumptives.

Personal.—Prof. Hans Meyer of Vienna will lecture October 4 and 5 on pharmacology in the Herter course at Johns Hopkins University.——Dr. H. Barton Jacobs has been named as one of the delegates to represent the United States at the Tuberculosis Congress in Paris, October 2 to 7.——Drs. T. Caspar Gilchrist and William H. Welch have returned from Europe.——Dr. Ira Remsen returned from Northeast Harbor, Maine, September 27.

After Many Days.—The mayor has signed the ordinance providing for the erection of an infectious diseases hospital on ground owned by the city near the Almshouse (Bayview Asylum). Plans will be prepared at once so that the building can be occupied as soon as possible. Thus at last, after twenty-five years or more, the authorities are about to provide for this so greatly needed institution.

MASSACHUSETTS.

Health Board Appointed.—Drs. Albert C. Lane, J. Henry Hutchings and Charles T. O'Brien have been appointed a Board of Health for Woburn.

Chronic Hospital Patients.—The latest report shows that there are 803 patients in the Boston Chronic Hospital, located on Long Island, Boston harbor.

Bequests.—By the will of Mrs. Marcia A. Norris, Boston, $5,000 is left to the Children's Hospital, $5,000 to the New England Hospital, and $4,000 to the Wellesley Convalescent Home for Children.

Hospital Music.—The hospital music fund, under the direction of Dr. John Dixwell, begins its work in October. Concerts will begin October 1 at the Home for Aged Women; October should not be neglected. The *suggestion that municipal* authorities inspect and enforce proper cleanliness and sanitary requirements in public restaurants is well worthy of attention. Moreover, the reform ought to be easy. If it were known which restaurants are worthy of public patronage in this respect, they would be likely to get it to the disadvantage of those that are not. There is a wide field for reform here not only in the methods and material outfit of these establishments, but also in their personnel.

THE HARVEY SOCIETY.

The Harvey Society of New York is described in its constitution as "a society for the diffusion of the knowledge of the medical sciences." The particular object, judging from the program of its first course of lectures, appears to be to bring the results of investigations in the medical sciences directly to those engaged in the practice of medicine as well as to others. The lectures are *given* under the auspices of the New York Academy of Medicine. The program[1] of the course for 1905-6 includes lectures by Professor Hans Meyer on "Die Theorie der Narcose;" Professor Carl von Noorden, "Modern Problems in Metabolism;" Professor F. G. Novy, "Trypanosomes;" Dr. R. A. Levene, "Autolysis;" Professor W. H. Park, "A Critical Study of Serum Therapy;" Professor L. F. Barker, "The Neurones;" Professor F. S. Lee, "Fatigue;" Professor L. B. Mendel, "The Formation of Uric Acid;" Professor T. H. Morgan, "Regeneration in Man and Other Vertebrates;" Professor C. S. Minot, "The Nature and Cause of Old Age;" Professor J. C. Webster, "Modern Views Regarding Placentation;" Professor Theobald Smith, "Some Phases of Tuberculosis," and Professor W. H. Howell, "The Cause of the Heart Beat." This is certainly a distinguished company, and the Harvey Society is congratulated on the solid attractiveness of its first annual program. It was a happy idea to establish a society of *this kind and purpose. It means a new agency for the* popularization, especially among the *medical men of* New York city, of the results of scientific investigation in various fields of medical and also general interest. Perhaps other medical centers may find it advantageous to establish somewhat similar means for the same general purpose.

---

1. For dates, etc., see General News, this issue.

Physicians' Fees.—There is, it seems to me, one just plan by which fees should be regulated. It is that the physician should have an estimate of the value of his services, operative *or otherwise*, fixed in his mind. The amount should be based on his experience and skill. It should not be so low as to coax away unjustly the patients of the younger and less experienced men of the profession. This fee should be lessened when the financial position of the patient would make its payment a serious burden. A well-to-do patient should pay the full fee, which should be generous in order to recompense the physician for his expensive education and hazardous life. This fee, however, should not be increased because the serv-
ices opportunity tn are utilized by a very wealthy person,
scientific subjects te is given to the service or an additional
on the physician by reason of the
present time. Dr. K Roberts.

Medical News

GEORGIA.

Changes in Atlanta College Faculties.—Dr. William S. Elkin has been elected dean of the Atlanta College of Physicians and Surgeons, to succeed Dr. William S. Kendrick, and Dr. Stephen T. Barnett, registrar; Dr. James B. Baird has been appointed professor of *principles* and practice of medicine; Dr. Charles G. Giddings, professor of clinical medicine; Dr. E. Bates Block, professor of clinical *medicine, and Dr. Cyrus W. Strickler*, associate *professor* of principles and practice of medicine. The faculty proposes to erect a new building to cost $75,000, of which $30,000 has already been subscribed.

New Medical School.—The Atlanta School of Medicine opened October 3 in its *temporary quarters in the* Masons' Annuity Building with the following faculty: Dr. Howard J. Williams, Macon, special lecturer on surgery; Dr. William S. Kendrick, professor of medicine; Dr. Charles D. Hurt, professor of therapeutics; Dr. George H. Noble, professor of abdominal surgery and clinical gynecology, dean of the faculty; Dr. James M. Crawford, professor of diseases of the eye, ear, nose and throat; Dr. Edward C. Davis, *professor* of gynecology and obstetrics; Dr. Luther C. Fischer, professor of anatomy and clinical surgery; Dr. Edward G. Jones, professor of gynecology and obstetrics, proctor of the *faculty*; Dr. Frank K. Boland, professor of operative and clinical surgery and demonstrator of anatomy; Dr. Hansell Crenshaw, professor of materia medica and chemistry; Dr. *Stewart* R. Roberts, professor of physiology; Dr. James L. Campbell, professor of surgical anatomy and clinical surgery; Dr. William L. Champion, *clinical professor of genitourinary* diseases; Dr. Robert B. Ridley, Jr., clinical professor of diseases of the eye, ear, nose and throat; Dr. L. Benjamin Clarke, lecturer on diseases of children, and Dr. James H. Crawford, assistant to chair of diseases of the eye, ear, nose and throat.

Plans will be prepared at once so that the building can be occupied as soon as possible. Thus at last, after twenty-five years or more, the authorities are about to provide for this so greatly needed institution.

MASSACHUSETTS.

Health Board Appointed.—Drs. Albert C. Lane, J. Henry Hutchings and Charles T. O'Brien have been appointed a Board of Health for Woburn.

Chronic Hospital Patients.—The latest report shows that there are 803 patients in the Boston Chronic Hospital, located on Long Island, Boston harbor.

Bequests.—By the will of Mrs. Marcia A. Norris, Boston, $5,000 is left to the Children's Hospital, $5,000 to the New England Hospital, and $4,000 to the Wellesley Convalescent Home for Children.

Hospital Music.—The hospital music fund, under the direction of Dr. John Dixwell, begins its work in October. Concerts will begin October 1 at the Home for Aged Women; October

8, at Channing Hospital; October 15, at Vincent Memorial Hospital; October 22, at Home for Aged Colored Women; October 27, at Franklin Square House, and October 29, at the House of the Good Samaritan.

Tuberculosis Camp a Success.—The camp on Parker Hill, Roxbury, maintained by the Boston Association for the Relief and Control of Tuberculosis, and started early in July, has proved a great success. It will be continued till about November 1. The total expense has been about $1,300. For this sum about forty-five patients have been cared for each day, returning to their homes to sleep.

Boston's Consumption of Water.—The city of Boston consumed during the month of August an average of 87,999,600 gallons of water each day. From the same metropolitan system there was furnished to seventeen other adjacent towns and cities a daily average of 27,433,200 gallons. This total daily average supply of 115,432,800 gallons exceeded the daily average consumption of August, 1904, by 6,412,300 gallons.

Sanitary Measures in Progress.—The big cofferdam, the first step in the construction of the great water park which is to be between Boston and Cambridge, so long urgently sought for by the Masachusetts Board of Health, is finished. So, too, is the cleansing of the ponds of the Back Bay fens where the foulness of sewers has for many years collected. Both of these will greatly promote the health of the neighboring residential portions of the city.

MICHIGAN.

Colleges Opened.—The formal dedication and opening of the new building of the Michigan College of Medicine and Surgery, Detroit, took place Sept. 19. On behalf of the alumni of the Association of the college, its chairman, Dr. Charles F. Kuhn, presented to the institution an oil painting of the dean, Dr. Hal C. Wyman.——The Grand Rapids Medical College opened for the fall and winter term September 26.

Personal.—Dr. A. Arthur McLarty, Manistee, has returned from Europe.——Dr. James Wright, formerly a practitioner of Jennings, has been committed to the Northern Michigan Asylum, Traverse City.——Dr. William K. West, Calumet, has been appointed head physician of the Copper Range Consolidated Company.——Dr. Joseph Foster has been appointed oculist and aurist, and Dr. Harry A. Haze medical examiner for the Lansing Suburban Traction Company.

NEW YORK.

College Opens.—The University of Buffalo Medical Department began the winter sessions Monday, September 25. Dr. George F. Cott delivered the opening address, in which he advocated a six-year course, saying that the present course of four years is not sufficient.

Personal.—Dr. H. Ernest Schmidt, White Plains, has returned from Germany much improved in health.——Dr. Albert E. Woehnert, Buffalo, has recovered from an operation for appendicitis.——Dr. Frank W. Hinkel, Buffalo, has returned from abroad.——Dr. Patrick A. Hourigan, Buffalo, who has been ill with blood poisoning, is recovering.——Dr. Bernard Bartow has returned from Wanakah.

The Water Supply.—The state water supply commission has asked the attorney-general whether the 200 private water companies in this state are subject to the control of the commission in like manner as are the municipal boards. One hundred questions relating to purity of water supply and disposal of sewage have been formulated, to be asked of the 906 villages, towns and cities of the state. The best water and filtration plants will be visited and the water supply of Buffalo and Niagara Falls will be investigated.

Many Consumptives Helped.—The trustees for the New York State Hospital for Incipient Pulmonary Tuberculosis, located at Ray Brook, have issued their completed statistics for the first year, which show an excellent percentage of recoveries and improvements. There were admitted 207 patients, more than half of whom were incipients. There were no deaths. Of 105 patients discharged, 52 were apparently recovered. There were reported 26 arrested cases, 16 improved, and 11 without improvement. These latter cases remained but a few weeks. Of the 105, 90 gained an average of 10.57 pounds each. The trustees of the hospital are Dr. Willis G. MacDonald, Albany; William A. Douglass, Buffalo; Dr. Elmer E. Larkin, Plattsburg; W. E. McClary, Malone.

New York City.

More Yellow Fever at Quarantine.—A coal passer aboard the steamer *Havana*, from Colon September 24, died from yellow fever on Swinburne Island September 26.——Five of the crew of the British steamship *Lindisfarne*, from Cienfuegos, have been held for observation. The vessel had been at Colon and several of the crew had been ill with the fever.

Contagious Diseases.—There were reported to the sanitary bureau for the week ended September 23, 350 cases of tuberculosis, with 142 deaths; 155 cases of diphtheria, with 18 deaths; 124 cases of typhoid fever, with 15 deaths; 69 cases of measles, with 1 death; 62 cases of scarlet fever, with 1 death; 11 cases of cerebrospinal meningitis, with 15 deaths, and 20 cases of varicella.

Herter Lectures.—The Herter Lectures, established by Dr. C. A. Herter at the New York University and Bellevue Hospital Medical College, will be given this year by Prof. Carl von Noorden, chief of the City Hospital of Frankfort, Germany. His subject will be "Diabetes." The six lectures will be given in English in the large auditorium of the Carnegie Laboratory, 338 East Twenty-sixth Street, from Monday, October 9, to Saturday, October 14, inclusive, at 4 o'clock in the afternoon. Visitors are welcome.

Fear an Eye Epidemic.—Several eye specialists declare that ophthalmia will follow the Mardi Gras carnival at Coney Island. Influence was brought to bear on the carnival committee which resulted in posters being freely displayed about Coney Island to warn confetti throwers that any person who gathers the torn bits of paper from the pavement and throws them at another person will be arrested and, if found guilty, will be punished by either a fine of $100 or six months' imprisonment. Physicians have treated several cases of iritis at the Coney Island Reception Hospital which have resulted directly from throwing confetti.

Personal.—Dr. Thomas Darlington, health commissioner of New York, addressed the workingmen of Hartford, Conn., September 25 on the subject of "Tuberculosis," treating his topic from the economic standpoint.——Dr. and Mrs. Morris L. King, who are making a journey around the world, have left India and started for London en route for New York.——Dr. John W. Robie returned from Europe on the *Ryndam* September 26.——Dr. E. Harrison Griffin returned on the *Minneapolis* September 26.——Dr. Milton J. Ballin returned on the *Hamburg* September 27.——Dr. Alma Vedin sailed for Europe on the *Finland* September 30.

Some Results of Food Inspection.—During the year 1904 food inspectors condemned and destroyed 2,000,000 pounds of meat. The small dealers and push-cart men are closely watched and frequently 5,000 pounds or more of their wares are destroyed in a single day. During the past year 848 samples of food-stuffs were subjected to analysis and this resulted in nearly 8,500,000 pounds being destroyed. There are about 1,500,000 quarts of milk shipped to New York daily and more than 30,000 samples are collected and analyzed in the course of a year. The fines last year amounted to over $10,000 and over 75,000 quarts were destroyed. It is said that the system of inspection of fruits is so rigid that it is next to impossible for a barrel of apples, a case of oranges or a bunch of bananas to slip through unnoticed.

Cripples Become Self-supporting.—The New York City visiting committee of the State Charities Aid Association reports that the inmates of one ward of the Home for the Aged and Infirm on Blackwell's Island, which is devoted to paralyzed, rheumatic and epileptic, were induced to take up bead work. The interest spread until 20 out of 60 men in the ward were at work. The Brooklyn division of the home has also taken up the work. Improvements have been installed in the farm colony on Staten Island. The dormitory has been enlarged and three cottages completed, providing room for about 500 inmates. The value of the farm products has increased from $5,000 in 1902 to $12,000 in 1904. In Brooklyn the committee found that present hospital facilities are inadequate and that there is great need for increased capacity in existing plants as well as for the establishment of several smaller hospitals.

College Opens.—At the opening of the College of Physicians and Surgeons in the City of New York, September 28, Dr. Samuel Lambert, dean of the college, delivered an address on "Some Present Fallacies in Medical Education." He declared that four months of vacation was too much. As most professors and students took up work during vacation it was surprising that the summer session was not better attended. The cause probably was that the subjects taken, except in two cases, were not counted for degrees. He suggested that the university change this. Another fallacy was trades unionism in medical education, inasmuch as the curriculum, like trades unions, limited the work to be done by its members. Another fallacy was the confirmed habit of the medical student to modify the existing curriculum to meet his individual ideas and his commonest error was to run away from the required duties to enter some hospital as a substitute for one of the house staff. The college should supply such work as a part of the curriculum.

OKLAHOMA.

Meeting of Southwestern Tri-state Medical Association Postponed.—Owing to the quarantine restrictions, the meeting of the Southwestern Tri-state Medical Association of Oklahoma, Indian Territory and Texas, at Oklahoma City, has been postponed from October 17-18 to November 8-9.

PENNSYLVANIA.

District Censors Chosen.—At the September meeting of the Huntingdon County Medical Society Dr. Charles A. R. McClain, Mount Union, was recommended for district censor.——Dr. W. D. Hamaker, Meadville, was chosen district censor by the Crawford County Medical Society.

National Guard Appointments.—Capt. Louis P. McCormick, Connellsville, has been commissioned major-surgeon in the N. G. Pa., and assigned to the Tenth Infantry.——Dr. James F. Elder, New Brighton, has been commissioned first lieutenant and assistant surgeon in the same command.

Philadelphia.

Personal.—Drs. Francis Packard and J. Norman Henry have returned from Europe.——Dr. Frank W. Lally was severely bruised in an automobile accident near Allentown, September 24.

Hospital Reports.—From August 24 to September 21 the German Hospital admitted 239 patients and discharged 200; 19 patients died and the number [illegible] atter date was 167.——The report of the [illegible] Hospital shows that an unusual amount of work was done in the hospital during the three months ended August 31, as 182 patients, including 19 remaining from May, were cared for in the hospital, receiving 2,204 days' support. In the out obstetric service 25 infants were born, necessitating 152 visits from physicians. Patients paid 447 visits to the several clinics and 417 prescriptions were compounded.

Health Report.—The total number of deaths reported for the week ended September 30 was 384, being a decrease of 25 from the preceding week and a decrease of 14 from the corresponding week of last year. Among the deaths 193 were of men, 191 of women, 73 of boys and 59 of girls. The principal causes of death were as follows: Typhoid fever, 14; tuberculosis, 45; cancer [illegible] 8; paralysis, 10; heart disease, 38; acute [illegible] 38; gastritis, 34; diarrhea, 31; Bright's disease, 17; premature birth, 14; congenital debility, 13; old age, 8; accidental injuries, 25; marasmus, 9. The number of cases of contagious disease reported for the week were: Diphtheria, 34; scarlet fever, 32; typhoid fever, 95, making a total of 161 cases, with 18 deaths, as compared with 184 cases and 13 deaths for the previous week.

Medical Colleges Open.—The opening exercises of the one hundred and fortieth annual session of the Department of Medicine of the University of Pennsylvania were held in the new medical laboratory, September 29. The principal address was delivered by Prof. Alfred Stengel. No important changes have been made in the courses, although the school has lost, by resignation, Dr. Alfred W. Miller, assistant professor of materia medica; Dr. Robert J. Formad, demonstrator of normal histology; Dr. John M. Swan, demonstrator and students' physician; Dr. George P. La Roque, assistant in surgery, and Dr. Samuel McClary, assistant demonstrator of normal histology. The following new men have been added to the teaching staff: Dr. Ewing Taylor, associate in anatomy; Dr. Henry L. Bates, assistant in physiology, and Dr. Rufus B. Scarlet, voluntary assistant demonstrator of pathology.——The annual session of the Medico-Chirurgical College convened September 25.——The annual opening of Jefferson Medical College was held September 25, and the annual address to the students was delivered by Hon. William Potter, president of the board of trustees.

Suppressing Abortionists.—No more serious duty has in recent years confronted regular practitioners than that of the enforced removal of the band of abortionists who seem to have made Philadelphia their headquarters. With this object in view a committee of three was appointed by the Philadelphia County Medical Society April 20, 1904, to aid the coroner, the director of public safety and the district attorney in the securing of evidence against and in the prosecuting of those performing criminal abortions. At the meeting of the society September 13 Drs. Francis M. Perkins, Charles W. Burr and Henry W. Cattell submitted the following report of their labors:

Your committee begs leave to report that it has investigated over thirty persons making a practice of performing criminal abortions in the city of Philadelphia and that at the present time each one of these has either left the city, is under police surveillance (6), is a fugitive from justice (7), is awaiting trial (7), or is in prison serving time (8).

Your committee in its entirety or individually has paid frequent visits to Coroner Dugan, District Attorney Bell, Director Smyth, and Director Potter, and have been most courteously received by these gentlemen and believe the support of the society in assisting them in the performance of their duties has been much appreciated.

As an additional example of what has been done may be cited the case of one of the Philadelphia newspapers which formerly carried in its Sunday edition 10 to 17 advertisements of criminal abortionists, and which now no longer prints this objectionable kind of matter.

So much having been accomplished it is hoped that the County Medical Society will never permit this nefarious business again to assume such vast proportions in Philadelphia as was the case in the early part of 1904. It would seem to the committee that the only way to prevent this now that the city is largely freed from criminal abortionists, is to have the matter taken up by the State Medical Society and the American Medical Association, so that when the abortionists are driven from one city they will not immediately go to another place and carry on work of a similar nature. Thus several years ago an earnest endeavor was made to drive this class of persons out of Boston and as a result Philadelphia received several of the worst specimens with which the authorities have had to deal. Then, too, it is so easy to live in New York or New Jersey and to come over to Philadelphia a certain number of days each week. If a central committee of the American Medical Association could be established with affiliating committees in the various large centers, your committee believes that much good could be accomplished thereby.

VIRGINIA.

Hospital Association Formed.—An association has been formed at Leesburg for the purpose of establishing a hospital. It will start with a capital of $2,000, to be later increased. Dr. Rebeka Wright of Washington, is at its head. The movement is receiving the active support of physicians in Leesburg and vicinity.

Doctors Object to Special License.—The *Medical Legislator*, published by the Medical Society of Virginia, contains articles condemnatory of the special license tax varying from $10 to $25 a year, which is now imposed on physicians. The aim of the society is to compel the repeal of this act. It is claimed that the medical is the only profession from which such license tax is exacted.

GENERAL.

Yellow Fever in Panama.—During the week ended September 9 four new cases of yellow fever were reported in the city of Panama, three of which were fatal. No cases have occurred in either Colon or Cristobal since August 26, and there have been no suspicious cases observed in the hospital since that date.

Health Report of the Isthmian Canal Commission.—The report for August calls attention to the continued excellent health conditions among the laborers working on the canal. It is stated that yellow fever is steadily decreasing; during August there were only 27 cases. This is the smallest number of cases since April. In May there were 33, in June 62, in July 42. The report also includes a description of the methods employed in inspecting houses and of notifying tenants that houses are in an insanitary condition. There is a detailed account of the general sanitary work done and of the results accomplished.

Death of Mr. W. B. Saunders.—Mr. W. B. Saunders, the well-known medical book publisher of Philadelphia, aged 47, died Monday, October 2. Mr. Saunders started medical book publishing in 1891, and in the short time since then, has built up one of the largest medical book publishing concerns in the country, if not in the world. His energy, his honesty of purpose and his genial disposition won him success and many friends in the medical profession. He leaves a wife and two children, the latter aged, respectively, 12 and 16. Mr. Saunders has been ill and unable to attend to his business for several months. We understand that the business will be conducted as heretofore.

Health of the Non-immune Employes of the Canal Commission.—The Public Health and Marine-Hospital Service reports that the health of the non-immune employes of the canal commission residing at Cristobal is at present exceptionally good, no cases of yellow fever having occurred among them during the past month, and the number of cases of malaria having greatly diminished. This is undoubtedly due to the improved sanitary conditions, mosquito work and screening of the living quarters. Strong westerly winds have also contributed to keeping the town comparatively free from the swarms of mosquitoes from the surrounding swamps. A general feeling of encouragement prevails, but the efforts and vigilance of the sanitary department are in no wise being relaxed. It is proposed by the sanitary department to keep the large numbers of non-immunes arriving on the isthmus out of the sphere of infection as far as possible. A camp in the canal zone along the line of the railroad is to be established, to which the new arrivals are to be taken and where they will be held until they can be distributed to points outside the cities of Colon and Panama. This is considered especially advisable in the case of the Colombian laborers, many of whom come from the mountainous interior.

Health in the Philippine Islands.—The report of the Board of Health of the Philippine Islands for June shows that 600 births were registered during the month. Of these 326 were males and 274 females. The report states that if these were the only births that occurred the birth rate would be 32.67 per thousand, but as it is positively known that many births were not reported it is impossible to state the exact birth rate. During the month 583 deaths were reported, of which 526 were of residents and 57 of transients. Convulsions of children caused 108 deaths, the largest number from any one disease; pulmonary tuberculosis caused 90; diarrhea and enteritis (under 2 years), 32; chronic enteritis, 30; dysentery, 29; congenital debility, 26; meningitis, 24; bronchitis (acute and chronic), 42; beriberi, 14; cerebral congestion and hemorrhage, 14; other diseases, 88. The mortality among children belonging to the groups of under thirty days and from thirty days to a year is the lowest proportion which has been observed up to the present time. Three deaths were registered in Cebu and one in Cavite from bubonic plague. The prophylactic measures which have been carried on with perseverance and activity have yielded the expected results and the archipelago has been practically freed from the former yearly epidemic of this disease.

Yellow Fever.—The figures are as follows in New Orleans: Total cases to October 2, 3,042; total deaths, 394; death rate, 12.9; new cases week September 26 to October 2, 185; deaths, 23; cases under treatment October 2, 204. In Louisiana, outside New Orleans, twenty infected points for the week September 25 to October 1 report 121 new cases. In Mississippi, week September 26 to October 2, Natchez has 29 new cases, making to October 2 a total of 102 cases and 6 deaths—a death rate of 5.8 per cent. Vicksburg has 43 new cases, 5 deaths, making to October 2 a total of 115 cases and 14 deaths—a death rate of 12 per cent. Eight other infected Mississippi towns report for the week September 25 to October 1, 66 new cases and 1 death. In Florida, Pensacola has: Total cases to October 2, 163; deaths, 27; death rate, 16.6 per cent.; new cases September 26 to October 2, 58; deaths, 9. Under the charge of Dr. Chassaignac, the situation at Tallulah, La., has very greatly improved. Armed with a permit from the Mississippi Board of Health, Dr. Chassaignac set out to visit his home in New Orleans. In passing through Jackson, Miss., local quarantine guards refused to recognize his permit and even used physical violence to keep him from changing cars.——Business and pleasure in New Orleans are resuming normal activity.——Three additional cases of yellow fever have occurred among refugees in Cincinnati.——A death from yellow fever occurred at the New York quarantine.——The Arkansas quarantine is being slightly relaxed.——Georgia has quarantined against the whole state of Mississippi.

FOREIGN.

Royal Medical and Chirurgical Society of London.—The hundred and first session of this society will commence Oct. 24, 1905.

Enteric Fever in Germany.—During the early part of September enteric fever was practically epidemic in Posen. The total cases reported till the end of the month was 305.

Cholera in India.—The cholera epidemic in Madras seems to continue unabated, the daily returns being still very high. It is reported, according to *Public Health Reports*, that outbreaks have occurred in both the general hospital and the government lunatic asylum. A number of schools and colleges are closed.

Simple Test for Blood in Urine.—Sabrazès adds 10 drops of hydrogen dioxid to 10 c.c. of the urine to be examined. In the presence of even microscopic amounts of blood the fluid bubbles up and the froth is more abundant and lasts longer than when the bubbling is due to the presence of pus or alkaline salts. In normal urine only a very few bubbles are observed.—*Nord Médical*, September 15.

Openings for Physicians in Foreign Countries.—A committee was appointed by the medical society at Liège, Belgium, to investigate the chances for openings for Belgian physicians in other countries. The only lands that offer any chances for success, according to the report recently presented by the committee, are the East Indies, Persia, Asiatic Turkey, Egypt, Morocco, Haiti, Mexico, San Domingo, New South Wales and Southern Australia. Even in these countries the foreign physician can not rely much on any resources except his private means. The report urges the establishment of a postgraduate clinic on tropical diseases at Antwerp.

Smallpox Epidemic in Southern Africa.—Johannesburg is facing an epidemic of smallpox attributed to infection from letters sorted out by a mail clerk suffering from smallpox. Over 2,000 persons received letters which had passed through his hands, according to cable reports, and the persons affected are mainly Europeans. The more crowded native quarters have been comparatively exempt so far.

French Physicians' Finances.—At the inauguration of the Normandy Medicolegal Society Professor Brouardel of Paris stated that the pecuniary condition of physicians in Paris was worse than it was 30 years ago. When he was elected president of the Association of Physicians of the Seine district, 18 years ago, only $6,000 had to be disbursed for the assistance of orphans and widows of members during the year, while last year the disbursements for this purpose were over $12,400 and the amounts had been reduced from $180 to $140.

Russian Physicians Delay Return from War.—After the Russo-Turkish War fully eighteen months elapsed before the majority of the physicians of the campaign had returned home. They did not feel at liberty to return as long as their hospitals contained severely sick and wounded patients. The *St. Petersb. med. Wochft.*, commenting on this fact, remarks that it will probably be more than two years before the physicians in the far East can return to their home duties in Russia. Many parts of Russia are suffering from a lack of medical attendance owing to the absence of the regular physicians in the East.

International Radiology Congress.—The Roentgen Congress had but scarcely closed its doors at Berlin when a congress devoted to radium and radiology in general was planned. The Belgian government has perfected its organization, in connection with the international exposition now being held at Liège. Radium, radioactivity, the radium rays and their application in therapeutics, etc., are to be the main subjects discussed. The list of speakers includes Henri Becquerel, the discoverer of the radioactive substances; Svante Arrhenius, the great authority on physical chemistry; Birkeland of Christiania; Sir William Ramsay of London; Himstedt, Riecke, Righi of Bologna; Lassar of Berlin, and others.

New Biophysical Journal.—The publishing house of Gebrüder Borntraeger, Berlin, announces the publication of the *Biophysikalisches Centralblatt*, an organ devoted to collecting summaries of what is written on the subjects of biology, physiology and pathology, excluding biochemistry. It is to form the second part of the *Centralblatt f. d. gesamte Biologie.* The volume is to cost $7.50, except to those already subscribers to the *Biochemischen Centralblatt*, who can obtain it at reduced rates. The editors are C. Oppenbeimer and L. Michaelis of Berlin, with collaboration of Hertwig, von Leyden, Kraus and Orth of Berlin, Tigerstedt of Helsingfors, Hering of Leipsic and Biedermann of Jena.

Infant Mortality in Various Countries and International "Drop of Milk" Congress.—The percentage of deaths of infants under one year in the general mortality is 42 in Saxony, 38 in Bavaria, 33.9 in Prussia, 31.8 in Austria, 26.1 in Cuba, 19.2 in the United States, 17.4 in Sweden, and only 15 in France. The low infant mortality in France is due in large part to the Roussel law, the law passed in 1874 by the efforts of the physician and senator, Dr. Roussel, which ensures medical and police surveillance of every child less than 2 years of age who is boarded out. This custom of giving infants out to nurse and be cared for is very prevalent in France. The infants are generally placed in country homes, and are supposed to have the benefit of pure air and milk. Another factor in the low infant mortality in France is the "infant consultations" frequently mentioned in these columns (see page 1033), with their milk supply departments. An international conference of all interested in these "infant consultations" is to convene at Paris October 20-21. The secretary and treasurer is Dr. Paul Roger, 39 rue de Berry, Paris.

An International Congress Where All Spoke the Same Tongue.—International congresses are generally a confusion of tongues, discounting the Tower of Babel for the effect produced, but a congress was held recently at Boulogne, France, where all spoke esperanto. This is the artificial language invented by a Polish physician in 1887, which has been slowly gaining ground during the years since in spite of numerous criticisms of its defects. A French exchange describes the congress as a gathering of 1,500 members who were able to converse with each other on the common ground of esperanto, although coming from the remotest corners of the civilized world. Dr. Zamenhof's grammar of esperanto has been translated into 28 languages, and there are 20 monthly journals devoted to its propaganda. At Paris alone 30 public courses of lectures on esperanto were held last winter. The jealousy of the various nations prevents the general adoption of any one language for the common tongue for scientists of all lands. It actually seems as if some artificial language might answer the purpose, but it should be one based on the terms common to all the tongues in current use and not an arbitrary coining of uncouth sounds which has been the defect of the various artificial languages hitherto proposed.

Antituberculosis Congress.—Elaborate preparations have been made for the great antituberculosis congress which opens this week at Paris. More than 3,500 members are said to have registered, coming from all quarters of the globe, 33 countries having organized national committees of propaganda for the congress and appointed delegates. The delegates repres[illegible] thorities not only of medicine, but also of [illegible] of sickness and life insurance interests, of hygiene and of sociology. France has been divided into districts in which the question of tuberculosis among the population has been studied along the most improved lines, the data collected presenting several new features. The antituberculosis museum is to remain as a permanent exhibition. One of the exhibits is two contrasting rooms. One is fitted up by the Touring Club and shows a model hygienic and attractive room. The other, with curtains, carpets, poor lighting and ventilation, shows what not to do to avoid tuberculosis. Our French medical exchanges regard the congress as a week destined to mark history. The fee of $5 entitles to the transactions with 46 addresses, the preliminary report with abstracts of the addresses in English, French and German, to a pamphlet containing all the data in regard to the battle against tuberculosis in France, with other publications and the insignia of the congress, a beautiful little souvenir by a prominent artist.

Epidemics in Europe.—Cable dispatches dated October 3 state that no new cases of cholera developed during the preceding twenty-four hours, and only four in the twenty-four hours before that. The German authorities are much gratified at the workings of the measures taken against the disease. Although cases have occurred in more than fifty different localities, yet none has developed into a local focus. All can be traced to river traffic, and the rivers have been subjected to vigilant supervision. Every vessel is inspected by a physician once a day at least. The prophylactic measures have proved practicable and efficient, and the policy of absolute openness in regard to the cases has proved very reassuring to the public. The Moabite Hospital at Berlin has had a special building set apart for cholera patients, with a second barracks for the suspicious cases and a third for the attendants. In case of an epidemic, the entire hospital is to be devoted to cholera patients. The people are warned to boil the water, particularly as a number of cases of typhoid have occurred. The *St. Petersb. med. Wochft.* for September 16 reiterates that no cases of cholera have been reported in the Russian Empire. Our German exchanges have ceased to mention the epidemic of cerebrospinal meningitis, which seems to have died out, no new cases having been reported for some time. The total number of cases since the first was reported last November has been 3,250, with 1,750 deaths.

Early Diagnosis of Pregnancy.—Weissenberg writes from southern Russia to the *Allg. med. Ct.-Ztg.* for September 16, to call attention to the difference in the consistency of the two halves of the uterus in the first months of pregnancy. He has examined 120 pregnant women to determine the frequency of this variability in the consistency of the halves, and found the left side soft and the right hard in 6 women by the fifth week, in 28 by the sixth week, in 7 by the seventh week, in 12 by the eighth week, in 12 by the tenth, in 7 by the twelfth and in 1 by the fourteenth week. He found the right side soft and the left hard in 2 women in the fifth week, in 11 in the sixth week, in 3 in the seventh week, in 10 in the eighth week, in 5 in the tenth week, in 3 in the twelfth and in 1 in the fourteenth week. The livid aspect of the vagina mentioned by some writers as an early sign of pregnancy was observed very pronounced in 5 women in the sixth week, in 1 in the seventh, in 10 in the eighth week, in 8 in the tenth week, in 7 in the twelfth week and not afterward, while there was no livid appearance in 5 by the fifth week, in 20 by the sixth week, in 4 by the seventh week, in 6 by the eighth week and in the same number in the tenth week. The introitus was slightly livid in 2 women in the fifth week, in 13 in the sixth, in 10 in the seventh, in 6 in the eighth, in 3 in the tenth, in 2 in the twelfth and in 2 in the fourteenth week. The women were examined from week to week. He adds that the peasants are now as averse to large families as the dwellers in city flats, and the women are becoming ingenious in devising excuses for curettement, etc., to trap the physician into terminating the pregnancy.

Third Scientific Latin-American Congress.—This congress opened under favorable auspices August 6, at Montevideo, Uruguay, the presence of the president of the republic and of the entire diplomatic corps lending brilliancy to the inauguration. Delegates from all the Latin-American countries were in attendance, and much attention was devoted to interstate sanitary co-operation, measures to curb the white slave trade, arrest the spread of alcoholism and of various diseases, etc. The *Brazil-Medico* has already begun to publish summaries of some of the addresses, among them of Carrasquilla's article on leprosy. He preaches that leprosy is not contagious, but that it is infectious, and that it is transmitted by the flea. The first manifestation of the disease is a pustule, similar to the bubo of syphilis and of plague. It is not transmitted by the secretions nor by water nor by direct contact, but only by the intermediation of the flea. Isolation is absolutely unnecessary, freedom from vermin ensuring non-infection of others. J. Novaes described a form of beri-beri, accompanied by anesthesia to heat and pain in certain regions. He has always obtained good results from copious venesection and saline infusion, with dietetic and diuretic measures, sometimes applying leeches along the spine, in the triangle of Petit and in the popliteal space. The forms with anesthesia display a tendency to a more chronic course. In regard to plague, Moniz remarked in regard to the prevalent opinion that the plague patient recovers if the bubo suppurates, that suppuration occurs because the patient has survived long enough for this to happen. Moniz of Bahia proclaimed the great value of serotherapy of the plague as an adjuvant.

LONDON LETTER.

Self-supporting Sanatoria for the Treatment of Consumption Among the Working Classes.

An organization has been formed to carry out this object. Its importance is shown by the fact stated at the last annual meeting of the Hospital Saturday Fund that in London alone 16,000 persons, whose lives might be saved by proper treatment, annually die from consumption. It is computed also that in London 80,000 persons suffer from one or other form of tuberculosis. A national committee of which the Princess Christian is president has been established under the auspices of the Hospital Saturday Fund for the establishment of sanatoria for workers suffering from tuberculosis. It is an exceptionally representative body and includes delegates from practically all the great friendly societies and trade unions. An appeal is being made to the public for $250,000 to provide a building and to acquire a site for the first sanatorium for the accommodation of 200 patients. About $30,000 has already been promised and a suitable site has been secured at Benenden in Kent. The various societies and trade unions guarantee the cost of maintenance, but under the terms of their constitutions they can make only small donations toward the building. The sanatorium will thus be self-supporting and no appeal will ever again be made to the public for funds. An investigation made by the Ancient Order of Foresters is interesting in this connection: The average cost of sick pay to a consumptive is three times as great as that to a person dying from another disease.

Outbreak of Typhoid Fever Due to Shellfish.

In the neighborhood of the Teign in Devonshire an outbreak of typhoid fever has occurred which has been proved to have been caused by the consumption of cockles taken from that river. The local health officer has issued a notice advising people to refrain from eating shellfish, most of which is collected from the rivers into which large quantities of sewage are poured. The pollution has been going on for years and every year about the months of August and September a number of cases of typhoid fever occur.

Penalty for Facilitating the Spread of Disease.

A young man was charged before a magistrate with walking about and mixing with the public while suffering from diphtheria. He suffered from sore throat and went to a hospital, where the house physician told him he was suffering from diphtheria and must be at once isolated and sent to the fever hospital. He, however, left the hospital, promising to return in an hour, which he did not do. The house physician had no power to detain him, but reported the case to the sanitary authorities. The diagnosis was verified by the culture test. Three days later the man went to a physician who at that stage failed to recognize the disease and told the man he might go to work. The patient did not tell him that diphtheria had been diagnosed. The magistrate severely admonished the man and fined him $25.

The Open-air Treatment of Acute Disease in Children.

At the Northeastern Hospital for Children, situated in one of the poorest districts of London, an advance has been made beyond that of similar institutions in the open-air treatment of both acute and chronic diseases in children. A striking feature of this hospital is the open-air balconies which front the main building. Here all through the summer months the sick children may be seen lying out of doors in their cots and the operations of the wards being conducted in the open air. Cases of pneumonia, typhoid fever, summer diarrhea and other acute diseases are being treated with the greatest benefit. It has been found, however, that certain diseases are not amenable to this treatment, for example, heart disease. This appears to be due to the noise and bustle of the traffic of the populous street below in its passage over the stone blocks of the roadway. But these cases have done remarkably well since the treatment has been conducted in the open air at the back of the hospital, removed from the sight and sounds of the traffic. It is suggested that the work of the hospital would be assisted if the roads were paved with wood instead of stone. The balconies have been found especially useful in the case of young children who are convalescing. These children would no doubt be better at the seaside or in the country, but, unfortunately, children under the age of 3 are not admitted to convalescent homes. On the balconies delicate, puny, wizen-faced children put on flesh and become rosy and buoyant—a result which could not have been attained had they been drafted straight away to their homes in the slums. In Liverpool also the increasing need for the open-air treatment of disease in children has been realized. In 1899 a ward containing twenty beds was opened for this purpose at the West Kirby Home for Convalescent Children—a Cheshire seaside resort. Soon a permanent hospital containing 200 cots will be erected. During the greater part of the day the children at West Kirby are, when weather permits, in the open air. When it is wet and cold they are sent to a well appointed sun room. In the summer the doctors visit many of their patients in the grounds of the hospital. This scheme deals only with the more chronic cases of illness in children. The advantage of treating acute disease in children in the open air had not been put into practice before the London Northeastern Hospital adopted it. These results may be compared with those obtained in the floating hospitals of New York.

The Use of Boric Acid to Preserve Milk.

The vexed question as to the use of boric acid as a preservative of milk has again occupied the courts. As usual, the medical evidence was conflicting. At Wakefield a dairy company was charged with selling milk adulterated with boric acid to the amount of 4.8 grains to the pint. Dr. Kaye, the health officer, said that he thought that the use of boric acid was not only injurious to health, but was a dangerous cloak for insanitary conditions in connection with milking. For the defense Dr. Bradshaw of Liverpool stated that the disuse of milk preservatives in Liverpool during the last year greatly increased the infantile death rate, chiefly from diarrhea, as the milk without the use of preservatives rapidly became putrescent. Dr. Bradshaw held that the administration of small doses of boric acid was not injurious to health, while the conditions under which the milk is kept by the poor are such that if preservatives are not used decomposition with its attendant dangers is certain to occur. The case was dismissed, as the bench was not satisfied that boric acid in the quantity specified was injurious.

"Return Cases" of Fever.

The Metropolitan Asylum's board has issued an important memorandum with reference to "return cases" of scarlet fever and diphtheria. During twelve months there have been 688 alleged infecting cases of scarlet fever, amounting to 4.1 per cent. of the total number of patients discharged. Of this number 46.5 per cent. appeared to cause "return cases." There is no laxity in the discharge of patients, but "return cases" seem to be due to premature discharge. It is thought that more extended means of isolation than at present exists might result in a considerable reduction in the number of "return cases."

Research in Tropical Diseases in India.

A scheme for the provision of more adequate means of studying diseases in India has recently been considered by the government of that country. From time to time various plans have been discussed, but financial and other difficulties have prevented the adoption of a complete scheme. The brilliant work accomplished by some officers under circumstances of great difficulty and the successful administration of the Pasteur Institute at Kasauli, has led the government to hope that if the means are supplied they will obtain from among their officers a staff of scientific workers worthy of the problems that confront them. A new scheme is to be introduced which will render it unnecessary for officers to go from India to Europe to study the bacteriology and parasitology of tropical diseases. It is expected that workers from Europe will seek Indian laboratories to use the unrivaled material which the country affords. The government scheme comprises the establishment of a central research institute at Kasauli and a laboratory for scientific, medical and sanitary work at the headquarters of each provincial government. The functions of the central laboratory will be original research, the preparation of curative sera and the training of scientific workers. The functions of the provincial laboratories will be primarily the provision of expert assistance for the provincial medical and sanitary officers, but the superintendents of these laboratories will be encouraged, as far as opportunities allow, to prosecute original research. Kasauli possesses great advantages for the central laboratory. Its climate is temperate, it is easy of access by rail, it is the site of the Pasteur Institute and large hospitals are near. The first director of the central research institute will be Lieut.-Col. Semple, M.D., whose successful administration of the Pasteur Institute has marked him as possessing the zeal and capacity necessary for the great task before him.

A New Departure in the Management of Outpatient Departments.

The complaints of the profession against the abuse of hospitals, particularly of the outpatient departments, by patients well able to pay for medical assistance, are as persistent as they are futile. A new system which has been adopted in one of the smaller London hospitals, the Bolinbroke at Wandsworth, however, seems to have solved the difficulty. Casualty patients are seen only once unless they bring a card signed by a physician. The same principle is observed in the outpatient department proper. Patients are not admitted unless they are accompanied by their physician or bring a card or letter from him. After the patient is examined he is given a letter addressed to his physician, containing the opinion of the hospital physician or surgeon on the case and his advice as to treatment. No medicines are dispensed and any that are required must be obtained through the patient's physician. This plan has been carried out for several years with success.

The Declining Birth Rate and Physical Degeneration.

Two topics are now furnishing standing subjects for discussion in the lay press and are attracting an enormous amount of attention—the declining birth rate and the physical degeneration of the working classes associated with town life. Medical authorities, church dignitaries and public men of all kinds are entering into the discussion, which is conducted largely in an alarmist spirit, many declaring that the empire is being endangered. As to the birth rate, in 1903 the London rate was 28.4 per 1,000—the lowest then recorded and 0.1 below the preceding year. Now it is announced that the birth rate for Great Britain in the second quarter of the present year was only 27.8—the lowest recorded in any second quarter since civil registration was established. In 1895 the birth rate was 30.3, and in every succeeding year a decline has been recorded; in 1904 it was 27.9. Among the causes assigned are the "no family" and the "limited family" creeds, which the desire for a higher standard of life has engendered, and the diseases of women. The selfishness and desire for luxury and pleasure of the people are attacked by the critics, but they do not grasp the fact that the declining birth rate is a phenomenon of advancing civilization and an inevitable one. As to the physical degeneration of the population, the obvious conclusion from reliable data is that there is no such thing. Hence, the topic furnishes a splendid subject for discussion for all sorts of theorists, on the general principle which holds in medicine that the less there is actually known about anything the more can be said on it. No doubt town life, especially in the slums, is attended with certain injurious physical tendencies, but, on the other hand, the people are better fed to-day than ever before and the hygienic conditions of towns is much improved. Some time ago, as reported in THE JOURNAL, the director general of the army medical service showed by figures that the classes which furnish our armies with recruits are individually broader, heavier, taller and better constituted than ten years ago.

Pharmacology

"Scientfic Work Misrepresented and Commercialized."

PORTO RICO ANEMIA COMMISSION.
AIBONITO, P. R., Sept. 18, 1905.

To the Editor:—It has come to our notice that the report of this commission, published Dec. 1, 1904, is being used by the manufacturers of Gude's pepto-mangan to advertise their preparation of iron. As this advertisement puts us in a very unenviable and erroneous light before the medical profession generally, will you be kind enough to publish the following statement?

The advertisement in question purports to be a review of this report and, having attracted attention, proceeds by erroneous deductions and half-quotations in such a manner that one might believe the commission indorsed their preparation of iron as the best hematic in the treatment of the anemia of uncinariasis.

As a matter of fact, the report (page 119) clearly states that we found the carbonate of iron to give the best results. Our report, on account of the limited edition, has never reached the majority of our professional brethren, and for this reason we quote the portion referred to:

"It will be noticed that slight cases readily recover without iron, and here the difference in the tables is more marked, while there is less difference among the marked cases in proportion to their number. In other words, the more resistant cases of all grades received iron, but even then did not generally recover as rapidly as those less rebellious without, for while ferruginous preparations seem to act readily in some instances, still, in the majority, its effect was not marked. The rapidity of cure is due, apparently, more to the personal equation of the patient and the rapidity with which the parasites are expelled, than to the amount of reconstructive treatment. Thus it is quite difficult accurately to judge the comparative value of different iron preparations, yet it was noticed, even by some patients, that Blaud's pills gave more rapid results."

We do not believe that a perusal of the histories of the eighteen cases which the advertisement quotes demonstrates the superiority of pepto-mangan (Gude), as these patients recovered more slowly than others of the same type who took Blaud's pills or Vallet's mass. In fact, on account of this slow recovery the carbonate of iron was substituted for pepto-mangan in five of the eighteen cases (Cases 8, 9, 10, 13 and 15). We ceased to use pepto-mangan and gave none to the later cases.

To support our statement we invite attention to the following figures taken from those given in the very report which the M. J. Breitenbach Co. cite as proving the superiority of their preparation:

There are sixty-one cases reported in full with complete blood records and clinical histories. In eighteen of them pepto-mangan was used save toward the termination of five of them, when Blaud's pills were substituted. In eleven cases Vallet's mass was used, supplemented by Blaud's pills. In twenty-nine cases Blaud's pills were used exclusively. Three cases have no bearing on the subject.

Reconstructive treatment.	Pepto mangan (Gude).	Blaud's pills.	Vallet's mass.
Average hemoglobin before treatment, per cent.	20.7	26.5	18.1
Average number days under treatment	80.7	47.9	69.8
Average gain in hemoglobin during treatment, per cent.	62.3	66.8	66.6

But to bring out the difference between these drugs more vividly eighteen pairs of cases of like type have been tabulated, whose initial hemoglobins absolutely or nearly correspond. One of each pair was treated by Blaud's pills, the other by pepto-mangan. The demonstration is all the more potent in that both drugs were used in their true rôle as blood regenerators, in conjunction with thymol administered to both alike.

Case. No.	Form of iron used.	Hemoglobin before treatment.	Days under treatment.	Total gain hemoglobin.
1.	Pepto-mangan ...	33	100	68
56.	Blaud's pills.....	33	56	70
3.	Pepto mangan ...	25	71	78
52.	Blaud's pills.....	25	36	75
4.	Pepto-mangan ...	28	97	72
50.	Blaud's pills.....	27	36	75
6.	Pepto-mangan ...	22	101	48
25.	Blaud's pills.....	22	43	78
7.	Pepto-mangan ...	10	63	93
28.	Blaud's pills.....	11	71	90
8.	Pepto-mangan ...	34	101	44
46.	Blaud's pills.....	35	36	69
9.	Pepto-mangan ...	20	99	83
43.	Blaud's pills.....	20	50	81
10.	Pepto-mangan ...	20	92	84
51.	Blaud's pills.....	20	50	63
11.	Pepto-mangan ...	32	95	48
47.	Blaud's pills.....	32	36	70
12.	Pepto-mangan ...	27	80	3
53.	Blaud's pills.....	25	50	84
13.	Pepto-mangan ...	14	94	95
23.	Blaud's pills.....	14	50	66
14.	Pepto-mangan ...	16	93	85
45.	Blaud's pills.....	16	57	46
15.	Pepto-mangan ...	11	84	99
22.	Blaud's pills.....	12	71	92
16.	Pepto-mangan ...	20	92	70
60.	Blaud's pills.....	19	28	71
17.	Pepto-mangan ...	9	36	6
21.	Blaud's pills.....	13	71	89
18.	Pepto-mangan ...	16	98	66
59.	Blaud's pills.....	18	53	57
19.	Pepto-mangan ...	28	49	75
42.	Blaud's pills.....	31	57	3
33.	Pepto-mangan ...	9	8	6
20.	Blaud's pills.....	22	27	48

That is to say, of eighteen pairs of almost identical cases, the initial average of hemoglobin percentage in the cases treated by Blaud's pills was 21.9; in those treated by pepto-mangan (Gude), 20.7; the average number of days under treatment was 48.7 in the cases treated by Blaud's pills; in those treated by pepto-mangan (Gude), 80.7; the average gain in hemoglobin under Blaud's pills was 68.1 per cent; under pepto-mangan (Gude), 62.3 per cent.

We tried to use a variety of iron preparations and were offered the pepto-manganates made by this company. We had no idea that this preparation differed essentially from any other pepto-manganate of iron, and it certainly may not, but had we considered the pepto-manganates of superior value as blood regenerators we would have said so. As it is, we have said the contrary and wrote this company to that effect at the time we became convinced of it.

This commission does not wish to be understood to consider the use of reconstructive treatment as a necessity in the anemia of uncinariasis. Such an idea is all the more absurd in view of the fact that in the 12,000 cases treated under its direction since June 1, 1905, comparatively little reconstructive treatment has been used, many cases receiving none at all. As our experience with this disease widens, our opinion is strengthened that anthelmintic treatment is not only curative, but promptly so, in the vast majority of cases, iron or no iron. Thanking you in advance for the use of your columns,

We are, very truly yours,
BAILEY K. ASHFORD,
W. W. KING,
PEDRO GUTIERREZ YGARAVIDEZ,
Members of the Commission.

The following resolutions were adopted at the annual session of the Washington County (Iowa) Medical Society, September 19:

> *Resolved,* That this society express its hearty appreciation and commendation to the Council on Pharmacy and Chemistry and to the Editor of THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION for the stand they have taken and for the valuable work already done in the analysis of proprietary remedies and the publication of the same in THE JOURNAL. We promise our support and co-operation to the Association toward the attainment of the desired results.

CLYDE A. BOICE, M.D., Secretary.

No False Labels.

But in my opinion the most objectionable form of food adulteration is that which seeks to deceive the consumer. This deception is practiced for the sole purpose of getting a higher price for a food product than could be had if the true composition of the substance were known. Mixtures of sweets and flavoring matters are sold as maple syrup, glucose as honey, oleomargarin as butter. Orange marmalade, straw-power to detain him, but reported the case to the sanitary authorities. The diagnosis was verified by the culture test. Three days later the man went to a physician who at that stage failed to recognize the disease and told the man he might go to work. The patient did not tell him that diphtheria had been diagnosed. The magistrate severely admonished the man and fined him $25.

The Open-air Treatment of Acute Disease in Children.

At the Northeastern Hospital for Children, situated in one of the poorest districts of London, an advance has been made beyond that of similar institutions in the open-air treatment of both acute and chronic diseases in children. A striking feature of this hospital is the open-air balconies which front the main building. Here all through the summer months the sick children may be seen lying out of doors in their cots and the operations of the wards being conducted in the open air. Cases of pneumonia, typhoid fever, summer diarrhea and other acute diseases are being treated with the greatest benefit. It has been found, however, that certain diseases are not amenable to this treatment, for example, heart disease. This appears to be due to the noise and bustle of the traffic of the populous street below in its passage over the stone blocks of the roadway. But these cases have done remarkably well since the treatment has been conducted in the open air at the back of the hospital, removed from the sight and sounds of the traffic. It is suggested that the work of the hospital would be assisted if the roads were paved with wood instead of stone. The balconies have been found especially useful in the case of young children who are convalescing. These children would no doubt be better at the seaside or in the country, but, unfortunately, children under the age of 3 are not admitted to convalescent homes. On the balconies delicate, puny, wizen-faced children put on flesh and become rosy and buoyant—a result which could not have been attained had they been drafted straight away to their homes in the slums. In Liverpool also the increasing need for the open-air treatment of disease in children has been realized. In 1899 a ward containing twenty beds was opened for this purpose at the West Kirby Home for Convalescent Children—a Cheshire seaside resort. Soon a permanent hospital containing 200 cots will be erected. During the greater part of the day the children at West Kirby are, when weather permits, in the open air. When it is wet and cold they are sent to a well appointed sun room. In the summer the doctors visit many of their patients in the grounds of the hospital. This scheme deals only with the more chronic cases of illness in children. The advantage of treating acute disease in children in the open air had not been put into practice before the London Northeastern Hospital adopted it. These results may be compared with those obtained in the floating hospitals of New York.

The Use of Boric Acid to Preserve Milk.

The vexed question as to the use of boric acid as a preservative of milk has again occupied the courts. As usual, the medical evidence was conflicting. At Wakefield a dairy company was charged with selling milk adulterated with boric acid to the amount of 4.8 grains to the pint. Dr. Kaye, the health officer, said that he thought that the use of boric acid was not only injurious to health, but was a dangerous cloak for insanitary conditions in connection with milking. For the defense Dr. Bradshaw of Liverpool stated that the disuse of milk preservatives in Liverpool during the last year greatly increased the infantile death rate, chiefly from diarrhea, as the milk without the use of preservatives rapidly became putrescent. Dr. Bradshaw held that the administration of small doses of boric acid was not injurious to health, while the conditions under which the milk is kept by the poor are such that if preservatives are not used decomposition with its attendant dangers is certain to occur. The case was dismissed, as the bench was not satisfied that boric acid in the quantity specified was injurious.

"Return Cases" of Fever.

The Metropolitan Asylum's board has issued an important memorandum with reference to "return cases" of scarlet fever and diphtheria. During twelve months there have been 688 alleged infecting cases of scarlet fever, amounting to 4.1 per cent. of the total number of patients discharged. Of this number 46.5 per cent. appeared to cause "return cases." There is no laxity in the discharge of patients, but "return cases" seem to be due to premature discharge. It is thought that more extended means of isolation than at present exists might [illegible] in a considerable reduction in the number of "return cases."

Research in Tropical Diseases in India.

A scheme for the provision of more adequate means of studying diseases in India has recently been considered by the government of that country. From time to time various plans have been discussed, but financial and other difficulties have prevented the adoption of a complete scheme. The brilliant work accomplished by some officers under circumstances of great difficulty and the successful administration of the Pasteur Institute at Kasauli, has led the government to hope that if the means are supplied they will obtain from among their officers a staff of scientific workers worthy of the problems that confront them. A new scheme is to be introduced which will render it unnecessary for officers to go from India to Europe to study the bacteriology and parasitology of tropical diseases. It is expected that workers from Europe will seek Indian laboratories to use the unrivaled material which the country affords. The government scheme comprises the establishment of a central research institute at Kasauli and a laboratory for scientific, medical and sanitary work at the headquarters of each provincial government. The functions of the central laboratory will be original research, the preparation of curative sera and the training of scientific workers. The functions of the provincial laboratories will be primarily the provision of expert assistance for the provincial medical and sanitary officers, but the superintendents of these laboratories will be encouraged, as far as opportunities allow, to prosecute original research. Kasauli possesses great advantages for the central laboratory. Its climate is temperate, it is easy of access by rail, it is the site of the Pasteur Institute and large hospitals are near. The first director of the central research institute will be Lieut.-Col. Semple, M.D., whose successful administration of the Pasteur Institute has marked him as possessing the zeal and capacity necessary for the great task before him.

A New Departure in the Management of Outpatient Departments.

The complaints of the profession against the abuse of hospitals, particularly of the outpatient departments, by patients well able to pay for medical assistance, are as persistent as they are futile. A new system which has been adopted in one of the smaller London hospitals, the Bolinbroke at Wandsworth, however, seems to have solved the difficulty. Casualty patients are seen only once unless they bring a card signed by a physician. The same principle is observed in the outpatient department proper. Patients are not admitted unless they are accompanied by their physician or bring a card or letter from him. After the patient is examined he is given a letter addressed to his physician, containing the opinion of the hospital physician or surgeon on the case and his advice as to treatment. No medicines are dispensed and any that are required must be obtained through the patient's physician. This plan has been carried out for several years with success.

The Declining Birth Rate and Physical Degeneration.

Two topics are now furnishing standing subjects for discussion in the lay press and are attracting an enormous amount of attention—the declining birth rate and the physical degeneration of the working classes associated with town life. Medical authorities, church dignitaries and public men of all kinds are entering into the discussion, which is conducted largely in an alarmist spirit, many declaring that the empire is being endangered. As to the birth rate, in 1903 the London rate was 28.4 per 1,000—the lowest then recorded and 0.1 below the preceding year. Now it is announced that the birth rate for Great Britain in the second quarter of the present year was only 27.8—the lowest recorded in any second quarter since civil registration was established. In 1895 the birth rate was 30.3, and in every succeeding year a decline has been recorded; in 1904 it was 27.9. Among the causes assigned are the "no family" and the "limited family" creeds, which the desire for a higher standard of life has engendered, and the diseases of women. The selfishness and desire for luxury and pleasure of the people are attacked by the critics, but they do not grasp the fact that the declining birth rate is a phenomenon of advancing civilization and an inevitable one. As to the physical degeneration of the population, the obvious conclusion from reliable data is that there is no such thing. Hence, the topic furnishes a splendid subject for discussion for all sorts of theorists, on the general principle which holds in medicine that the less there is actually known about anything the more can be said on it. No doubt town life, especially in the slums, is attended with certain injurious physical tendencies, but, on the other hand, the people are better fed to-day than ever before and the hygienic conditions of towns is much improved. Some time ago, as reported in THE JOURNAL, the director general of the army medical service showed by figures that the classes which furnish our armies with recruits are individually broader, heavier, taller and better constituted than ten years ago.

PORTO RICO ANEMIA COMMISSION.

AIBONITO, P. R., Sept. 18, 1905.

To the Editor:—It has come to our notice that the report of this commission, published Dec. 1, 1904, is being used by the manufacturers of Gude's pepto-mangan to advertise their preparation of iron. As this advertisement puts us in a very unenviable and erroneous light before the medical profession generally, will you be kind enough to publish the following statement?

The advertisement in question purports to be a review of this report and, having attracted attention, proceeds by erroneous deductions and half-quotations in such a manner that one might believe that the commission indorsed their preparation of iron as the best hematic in the treatment of the anemia of uncinariasis.

As a matter of fact, the report (page 119) clearly states that we found the carbonate of iron to give the best results. Our report, on account of the limited edition, has never reached the majority of our professional brethren, and for this reason we quote the portion referred to:

"It will be noticed that slight cases readily recover without iron, and here the difference in the tables is more marked, while there is less difference among the marked cases in proportion to their number. In other words, the more resistant cases of all grades received iron, but even then did not generally recover as rapidly as those less rebellious without, for while ferruginous preparations seem to act readily in some instances, still, in the majority, its effect was not marked. The rapidity of cure is due, apparently, more to the personal equation of the patient and the rapidity with which the parasites are expelled, than to the amount of reconstructive treatment. Thus it is quite difficult accurately to judge the comparative value of different iron preparations, yet it was noticed, even by some patients, that Blaud's pills gave more rapid results."

We do not believe that a perusal of the histories of the eighteen cases which the advertisement quotes demonstrates the superiority of pepto-mangan (Gude), as these patients recovered more slowly than others of the same type who took Blaud's pills or Vallet's mass. In fact, on account of this slow recovery the carbonate of iron was substituted for pepto-mangan in five of the eighteen cases (Cases 8, 9, 10, 13 and 15). We ceased to use pepto-mangan and gave none to the later cases.

To support our statement we invite attention to the following figures taken from those given in the very report which the M. J. Breitenbach Co. cite as proving the superiority of their preparation:

There are sixty-one cases reported in full with complete blood records and clinical histories. In eighteen of them pepto-mangan was used save toward the termination of five of them, when Blaud's pills were substituted. In eleven cases Vallet's mass was used, supplemented by Blaud's pills. In twenty-nine cases Blaud's pills were used exclusively. Three cases have no bearing on the subject.

Reconstructive treatment.	Pepto mangan (Gude).	Blaud's pills.	Vallet's mass.
Average hemoglobin before treatment, per cent.	20.7	26.5	18.1
Average number days under treatment	80.7	47.9	69 8
Average gain in hemoglobin during treatment, per cent.	62.3	66.8	66.6

But to bring out the difference between these drugs more vividly eighteen pairs of cases of like type have been tabulated, whose initial hemoglobins absolutely or nearly correspond. One of each pair was treated by Blaud's pills, the other by pepto-mangan. The demonstration is all the more potent in that both drugs were used in their true rôle as blood regenerators, in conjunction with thymol administered to both alike.

No False Labels.

But in my opinion the most objectionable form of food adulteration is that which seeks to deceive the consumer. This deception is practiced for the sole purpose of getting a higher price for a food product than could be had if the true composition of the substance were known. Mixtures of sweets and flavoring matters are sold as maple syrup, glucose as honey, oleomargarin as butter. Orange marmalade, straw-berry jam, etc., often contain little or none of the material whose name they bear. Wines are misbranded both as to their true character and the place where they were made. Whisky is sometimes a mixture of neutral alcohol, essences and coloring matters, with sometimes a bit of straight whisky for conscience sake. Jams, jellies and marmalades contain glucose, coloring matters and antiseptics, and preserved meats and sausages are colored artificially and preserved with borax.

This whole system of deception strikes at the very heart of honest trade. It is one of the strange things of commercial ethics that men are found who support such a system and yet would be quick to resent any imputation on their honesty. *What should the public require?*

1. Good laws, state and national, forbidding the addition of deleterious substances to foods.
2. Requiring each label to convey to the consumer a correct and complete list of all the substances not natural to the food in question which the package contains.

In other words: NO FALSE LABELS!—H. W. Wiley, M.D., in *Collier's Weekly*, September 30.

"Try Our Remedy, Doctor, Please."

This is always the final argument of the promotors of new drugs and serums. "We do not expect you to accept the claims made for the serum," writes one firm in urging a trial. The argument is a convincing one to many physicians who do "try" the remedy on the agent's say-so, especially if they receive, as is commonly the case, free samples. There is such an apparent show of fairness in the request.

Yet the reflecting physician must see that he does himself and his patients an injustice to "try" all the remedies he is requested to "try" by the manufacturers thereof. Certainly is unknown to him, or remedies made by houses unknown are unknown to him, or remedies made by houses unknown to him; and especially is this true of serum remedies.

A serum made against syphilis which the makers claim "absolutely eradicates the syphilitic infection" is now being extensively advertised and the physician is asked to "try" it, although he has no means of knowing what it contains save the say-so of those financially interested in its sale. Is it not worse than folly for the physician to "try" such a remedy made by a laboratory unknown to him? He might as well "try" a remedy handed to him by a barker at a county fair because assured by him in a loud voice that it absolutely eradicates syphilis and that there will be no recurrence of symptoms.

The physician should not "try" remedies merely because he is asked to do so, or to oblige a plausible agent, but only when they come to him well introduced by firms and physicians well known to him for their intelligence *and honesty.* It may be said that he should never try a new remedy brought to his attention by an unknown firm and of which he has no knowledge save that given him by the interested firm. As a matter of fact it is better for him to accept no free samples from traveling agents. He should be prepared to buy what remedies he desires to try. This plan at once places him on an independent footing and reduces to a minimum his temptations to "try" a new remedy simply because it costs him nothing.

The physician may be perfectly certain of one thing, viz., that chemical firms furnish free samples because and only because it is to their interest to do so; and very often the object of these firms is to use the physician as a medium or catspaw to enable them to sell their remedies afterward directly to the public. The physician who good naturedly "tries" the remedy which the agent of an unknown firm leaves never knows when he is acting such a regrettable part.

It behooves us all to examine well into the credentials of any remedy we propose to "try" if we are to do justice to our patients and to retain our own self-respect.

Pittsburg, Pa. Theodore Diller, M.D.

Dr. E. E. Glover, Terre Haute, Ind., writes that he has the page from the *Ladies' Home Journal* for September, entitled "Pictures that Tell Their Own Stories," neatly framed and hung in his office. He says that it "excites a surprising amount of interest and comment."

Correspondence

The Mosquito Theory in Text-Books.

Washington, D. C., Sept. 29, 1905.

To the Editor:—The proof that yellow fever is transmitted by the bite of infected mosquitoes of a particular variety was so promptly accepted by the medical profession of America and Europe, and time has so amply demonstrated the truth and completeness of Walter Reed's conclusions that it seems almost incredible that American text-books for students and practitioners of medicine in the present year should teach the theory of Sanarelli and either omit or fail to make clear what is one of the greatest medical discoveries of the age.

From the splendid "Medical Diagnosis" of Musser, last edition, Lea Brothers & Co., I quote:

"Yellow Fever.—The infection which we are about to consider is the latest of the epidemic and contagious disorders for which a definite causal micro-organism has been discovered. . . . The specific micro-organism is *B. icteroides* described by Sanarelli."

A brief description of Sanarelli's germ, and of the serum diagnosis of yellow fever is given, but not a word about the transmission of disease by mosquitoes, or the work of Reed and his associates.

The entire discussion of yellow fever is taken without change from a previous edition of the work, and we have here evidently an unintentional failure to bring a few paragraphs of this most excellent book up to date in the new edition.

In "A Text-Book on the Practice of Medicine," etc., by Dr. James Magoffin French, William Wood & Co., 1905, the author, in describing yellow fever, states: "The *Bacillus icteroides* of Sanarelli is now generally accepted as the cause," but he appears to believe that the said bacillus is carried by *Stegomyia fasciata!!!*

I write this in no spirit of criticism, but because I believe that the future safety of our southern states from this terrible disease can only be obtained by a universal acceptance by the people of the fact of mosquito transmission of the malady, and, therefore, that a statement of another and an exploded theory of causation in an important text-book of medicine is a serious blow to popular education in a matter of very great moment to our country. Walter D. McCaw,
Major-Surgeon, U. S. Army.

Warning—Fraudulent Magazine Agent.

Niagara Falls, N. Y., Sept. 26, 1905.

To the Editor:—I would like to warn physicians through The Journal of a man by the name of Charles Croft, who pretends to be an agent for the World's Clubbing and Subscription Co., of New York City. Mr. Croft's method is to offer several magazines at an exceedingly low price so that nearly every man that he approached in this city bought magazines of him. He sold me *McClure's*, the *Cosmopolitan*, *Everybody's* and the *Black Cat* for $2.00 a year. Mr. Croft is a man about 26 years of age, would weigh about 165 pounds, smooth face, light brown hair, is well dressed and has a very pleasing manner. I have communicated with the publishers of the magazines which he sold me and they inform me that no subscription has been received and that Mr. Croft is a swindler. F. N. C. Jerauld.

Embryo Specimens Wanted.

Columbia, Mo., Sept. 26, 1905.

To the Editor:—I am making a collection of human embryos, which are preserved permanently for research work in human embryology. Any specimens (especially of the earlier stages), which your readers may be able to contribute would be thankfully received. The best general preservative is 10 per cent. formalin or the strongest alcohol.

C. M. Jackson, M.D., Prof. Anatomy, Univ. of Missouri.

The Arkansas Board of Health.

Little Rock, Ark., Sept. 18, 1905.

To the Editor:—That part of the editorial in The Journal of September 16 on yellow fever which referred to the situation in Arkansas has suggested that a few facts be submitted concerning the recent state board of health episode.

For the last ten or fifteen years the Arkansas State Board of Health has had only a nominal existence, and has existed by law, but not by any material support from the state. Physicians accepting appointments thereon have done so as a courtesy to the governor making the appointment and as an acknowledgment of the honor which he thus sought to bestow. The hope, too, was indulged in by those interested that by keeping up the semblance of a state board of health the matter of obtaining proper recognition on the part of the legislature would be facilitated, and the board which only existed in name would then become one in reality and effectiveness. On July 31, 1905, the board met at the mayor's office in Little Rock. At this meeting the board consisted of the following members: Drs. G. M. D. Cantrell, president, R. B. Christian, secretary, W. H. Miller and W. B. Hughes, all of Little Rock, Drs. W. W. Jackson of Jonesboro, and J. R. Lynn of Hazen. The four members from Little Rock, constituting a quorum, were present.

At this meeting a state quarantine was declared against New Orleans and all other infected points. This was done with the understanding that all the rules and regulations of the quarantine thus announced would be strictly and rigidly enforced on the part of the governor of the state by the employment for this purpose of the Arkansas guard, or militia. The board received positive assurance through his private secretary, who was present, that this would be done. A conservative, but effective, quarantine along the southern and eastern borders of the state was thus instituted and successfully operated for nearly a month.

On August 27, at a conference in the governor's office, there being present the governor, the commander of the state guard and the president of the state board of health, the rulings and all authority of the state board were virtually set aside and the governor seemed to arrogate to himself entire control of the quarantine situation.

On August 28 the state board of health met and unanimously adopted, and ordered to be dispatched to the governor immediately, the following resignations of the four members present, constituting a quorum of the board:

> Little Rock, Ark., Aug. 28, 1905.
>
> *Gov. Jeff Davis.*
>
> *Dear Sir:*
>
> We, the undersigned members, constituting a quorum of the Arkansas State Board of Health, hereby tender to you our resignation and request your acceptance of same, to take effect at once.
>
> This action is taken because we do not desire longer to occupy positions of responsibility and at the same time to be interfered with and shorn of our authority as the state board of health. We instituted and, with the aid of the state militia, have successfully conducted until recently an effective and reasonable state quarantine. Not a case of yellow fever has made its appearance in Arkansas. We have earnestly advised the raising of all local quarantines within the state and the reliance altogether on the state quarantine, so that the business and social interests of the state might be as little interfered with as possible and the use of health certificates thus be largely obviated. We do not wish longer to be responsible for a quarantine we can not control, and one which, at first both effective and conservative, is now fast becoming a wild frenzied shotgun affair.
>
> G. M. D. Cantrell, *President.*
> R. B. Christian, *Secretary.*
> W. H. Miller,
> W. B. Hughes.

A day or two after this action was taken Dr. W. W. Jackson of Jonesboro sent to the governor his resignation. Dr. J. R. Lynn of Hazen, at the request of the governor, it is supposed, had resigned several days before. The resignations thus sent in were promptly accepted, and the following physicians were immediately appointed as members to constitute a new board of health for Arkansas and all accepted without delay: Drs. Joseph P. Runyan, president, Little Rock; Joseph P. Shephard, secretary, Little Rock; John R. Dibrell, Little Rock; Robert A. Hilton, Eldorado; Ben L. Harrison, Jonesboro, and Eugene H. Abbington, Beebe.

R. B. Christian.

Marriages

T. Ross Payne, M.D., Corbett, Md., to Miss Gent.

Louis R. Padberg, M.D., to Miss Mary Ring, at St. Louis, September 6.

Mortimer Frank, M.D., to Miss Donie Katz, both of Chicago, October 4.

Charles F. Buckley, M.D., to Miss Alice H. Osborne, both of Brooklyn, October 3.

Louis H. Friedrich, M.D., Chicago, to Miss Rose Rudolph of Milwaukee, October 5.

William H. Freeburger, M.D., to Miss Clara E. Pubbs, at Baltimore, September 19.

John E. Janes, M.D., Pasadena, Cal., to Miss Mary Marvin of Seattle, Wash., September 5.

William Johnson West, M.D., to Miss Marian Cottrell, both of Richmond, Va., October 3.

Oswald H. Magaret, M.D., Papillon, Neb., to Miss Malinda Leist of Lincoln, Neb., September 26.

Lewis W. Bremerman, M.D., New York City, to Miss Helen Tope of Oak Park, Ill., September 28.

William F. Berry, M.D., Glenwood, Mich., to Miss Harriet Alling of Evanston, Ill., September 16.

John Reynolds Patten, M.D., to Miss Augusta Eugenie Soule, both of Fairfield, Vt., October 3.

John Battle Carter, M.D., Milledgeville, Ga., to Miss Nellie Ferris of Augusta, Ga., September 21.

Clarence S. Latham, M.D., Hilliards, Ohio, to Miss Marie De Bolt of Columbus, Ohio, August 29.

J. A. Christenson, M.D., Manistee, Mich., to Miss Selma Rundquist of Ophiem, Ill., September 14.

Douglas Schoolfield, M.D., Bellevue, Ky., to Mrs. Clara Belle Gaff of Dayton, Ky., September 20.

John E. Dorman, M.D., Fayette, Iowa, to Miss Aurilla Cassidy of Raymond, Iowa, September 19.

William Wordsworth Riha, M.D., New York City, to Miss Emily L. Yursik of Baltimore, September 30.

Harman T. Haessig, M.D., to Miss Essie Graham, both of Paducah, Ky., at Metropolis, Ill., September 19.

Edmund R. Lape, M.D., Benson, Vt., to Miss Agnes Evangeline Peck of Fair Haven, Vt., September 20.

Frederick Philip Schultze, M.D., Marengo, Iowa, to Miss Mary Canon of Fremont, Iowa, September 27.

R. B. Cochrane, M.D., to Mrs. Lillian Griffith, both of Columbus, Ohio, in Covington, Ky., September 11.

Lake Louis Starkey, M.D., West Greene, Ala., to Miss Mary Bossworth of Birmingham, Ala., October 1.

William C. Pumpelly, M.D., Macon, Ga., to Miss Anne Altha Singleton of Fort Valley, Ga., September 14.

Cassius M. Clay Buchanan, M.D., Easton, Ill., to Miss Marguerite M. Saffer of Mason City, Ill., August 31.

William Whitney Kitchen, M.D., Buffalo, N. Y., to Miss Mabel Claire Money of Washington, D. C., October 4.

William J. Benner, M.D., Willow Lake, N. D., to Miss Etta Peeler of St. Louis, at Anna, Ill., September 21.

Moulton Kissinger Johnson, M.D., surgeon U. S. Navy, to Miss Schroeder, at Jamestown, R. I., September 16.

Julius Maltby Dutton, M.D., Tewkesbury, Mass., to Miss Charlotte Helena Coye of Livonia, N. Y., September 12.

Clinton Beecham Knapp, M.D., New York City, to Miss Mary A. Atwater, at Southington, Conn., September 20.

William Foster Huff, M.D., Los Angeles, Cal., to Miss Fannie Elizabeth Shallish of Riverside, Cal., September 28.

Frederick N. Henderson, M.D., to Miss Nellie F. Rayer, both of Philadelphia, at Mount Carmel, Pa., September 18.

Frederick William Harvey, M.D., Montreal, P. Q., to Miss Helen Margaret Ewing Riddel of Newark, N. J., at Newton, N. J.

Conrad Bell, M.D., Waltham, Mass., to Miss Elizabeth Prentiss Dudley of North Cambridge, Mass., September 21.

Allen D. McLean, M.D., passed assistant surgeon United States Navy, to Miss Sarah Moore of Detroit, Mich., October 2.

Joseph Arthur McClintock, M.D., New York City, to Miss Joseph Gilfelter of Wyoming, Pa., in New York City, September 19.

Robert Knight, M.D., Seneca Falls, N. Y., to Miss Clara Louise Carpenter of Greece, N. Y., at Rochester, N. Y., September 20.

Francis Merton Munson, M.D., passed assistant surgeon United States Navy, to Miss Katherine Glass, at San Francisco, October 3.

Archibald William Taves, M.D., to Miss Isabel Brydon, both of New York City, in the Royal Chapel of the Tower of London, September 21.

Deaths

James Read Chadwick, M.D. Harvard University Medical School, Boston, 1871, a prominent obstetrician and gynecologist of Boston; a founder and fellow of the American Gynecological Society, secretary from 1876 to 1882, and president in 1897; instructor in gynecology Harvard Medical School from 1873 to 1880, and from 1883 to 1887; physician to outpatient gynecological department of the Boston City Hospital from 1875 to 1882; president of the Harvard Medical Alumni Association from 1890 to 1893; vice-president of the Massachusetts Crematory Society since 1894; founder and librarian of the Boston Medical Library since 1875; a frequent contributor to gynecologic literature and for several years editor of the Transactions of the American Gynecological Society; corresponding fellow of the London Obstetrical Society from 1876 to 1900 and honorary fellow since 1900; honorary member of the Detroit Academy of Medicine since 1876, and of the Medical and Chirurgical Faculty of Maryland since 1896, was found dead just outside his summer home at Chocoma, N. H., September 24, aged 60. It is supposed that he became ill in the night and went out on the roof of the piazza to obtain fresh air, fainted and fell.

Josiah Hale, M.D. University of Louisville (Ky.) Medical Department, 1856, the oldest practitioner of Daviess County, Ky., delegates in 1876 and 1882 to the International Medical Congress; formerly a member of the American Medical Association, a member of the Tri-state Medical Society and of the Owensboro Medical Society, died at his home in Owensboro, September 14, after an invalidism of one year, from senile debility, aged 76. At a special meeting of the Owensboro Medical Society, September 14, a committee was appointed to draft resolutions regarding the death of Dr. Hale.

Arthur Weir Johnstone, M.D. New York University, New York City, 1876, of Cincinnati, a fellow of the American Gynecological Society; member of the Kentucky State Medical Society, Ohio State Medical Society, Cincinnati Academy of Medicine, Cincinnati Obstetrical Society and British Gynecological Society, prominent as an abdominal surgeon, died at his private hospital, Walnut Halls, Cincinnati, September 28, two days after an operation for appendicitis, aged 52.

Robert Brown Hammer, M.D. Department of Medicine of the University of Pennsylvania, Philadelphia, 1881, of Greensburg, Pa., coroner of Westmoreland County in 1884 and 1887; for several years state quarantine officer and president of the local board of health, died at the East End Hospital, Pittsburg, September 17, from septic peritonitis, one day after an operation for intestinal obstruction, aged 46. He had been ill for four years with disease of the intestines and had had several operations performed.

Peter J. Kirschner, M.D. Bellevue Hospital Medical College, New York City, 1879, physician of Buchanan County, Mo., 1880-1881 and 1889-1891; coroner of Buchanan County from 1882 to 1886; mayor of St. Joseph in 1898; president of the board of managers of State Hospital No. 2, St. Joseph, from 1889 to 1892, died at his home, September 22, from a nervous disease from which he had suffered for three years, aged 52.

Louis E. Hanmore, M.D. College of Physicians and Surgeons in the City of New York, 1884; a member of the Orange County (N. Y.) Medical Society; for eight years physician at the Newburgh city jail, and for three years surgeon to St. Luke's Hospital, died at the home of his mother in Newburgh, September 19, from pulmonary tuberculosis, after an illness of four years, aged 46.

Edward F. Galligan, M.D. Harvard University Medical School, Boston, 1881, a member of the American Medical Association, the Taunton (Mass.) Physicians' Club, and the Clover Club of Boston; city physician of Taunton in 1884, a member of the board of pension examiners for the district, died at his home in Taunton, September 25, after an illness of two years, aged 48.

John L. Long, M.D. University of Louisville Medical Department, 1878, formerly assistant physician at the Eastern Kentucky Asylum for the Insane, Lexington, and afterward superintendent of the Institution for the Education of Feebleminded Children, Frankfort, died from heart disease at his home in Normandy, Ky., after an illness of four days, September 27, aged 50.

Harry D. Hull, M.D. Bellevue Hospital Medical College, New York City, 1877; for three years city physician of Adrian, Mich.; for several years a member of the board of pension examiners and surgeon of the Wabash Railroad, died at his home, September 24, from locomotor ataxia, after an illness of several years, aged 51.

James Laws, M.D. Jefferson Medical College, Philadelphia, 1854 ;surgeon United States Navy during the Civil War; surgeon on one of Dr. Kane's Arctic relief expeditions; examining surgeon in the pension office, Washington, died at his home i nthat city September 11, after an illness of several months, aged 77.

George Burritt Nichols, M.D. Long Island College Hospital, Brooklyn, 1871, the oldest and best known practitioner in the San Luis Obispo County, Cal., aat one time mayor of San Luis Obispo and coroner of the county for seventeen years, died at his home September 21 from cancer of the ear and throat, aged 65.

William Patterson Hereford, M.D. University of Georgetown (D. C.) Medical Department, a highly respected practitioner of Prince George County, Va., the last survivor of the Seminole War, and a veteran of the Mexican and Civil Wars, died at his home near Wellington, Va., September 3, aged 89.

James Harrison Moore, M.D. Transylvania University Medical Department, Lexington, Ky., 1841, of Mercer County, Ky., representative from that county in the constitutional convention, died at the home of his son in Harrodsburg, Ky., September 16, after a protracted illness, aged 85.

John H. Sloane, M.D. Detroit (Mich.) College of Medicine, 1895, a promising young physician of Detroit, ruined by indulgence in alcoholics and morphin, died in an ambulance while being taken to St. Mary's Hospital, Detroit, September 26, aged about 38.

J. C. Gilbert, M.D. Barnes Medical College, St. Louis, 1899, an honor graduate of that institution; a member of the American Medical Association and of the Rockwall County (Texas) Medical Society, died at his home in Commerce, Texas, May 20, aged 36.

John Harrison Hunter, M.D. University of Maryland School of Medicine, Baltimore, 1855, a veteran of the Mexican War, and surgeon in the Confederate service during the Civil War, died at his home in Berkeley Springs, W. Va., September 26, aged 76.

William A. McPheeters, M.D. Department of Medicine of the University of Pennsylvania, Philadelphia, 1855, said to have been the oldest practitioner of Natchez, Miss., died suddenly on a train near Memphis, Tenn., September 27.

Thomas S. McKenna, M.D. College of Physicians and Surgeons, Keokuk, Iowa, 1880, of Manning, Iowa, died at St. Anthony's Hospital, Carroll, Iowa, September 22, two hours after an operation for urethral obstruction, aged 60.

John B. Hardeman, M.D. University of Nashville (Tenn.) Medical Department, 1872, died at his home in Henderson, Tenn., September 10, from jaundice, after a short illness, aged 69.

Charles W. Hamisfar, M.D. Ohio, 1871, died at his home in Fayetteville, Ark., September 10, from cancer of the intestines, aged 76.

Stephen J. Keyes, M.D. Long Island College Hospital, Brooklyn, N. Y., 1894, died at his home in Brooklyn, N. Y., September 14.

Arthur J. Harris, M.D. Chicago, 1887, died suddenly at his home in Grinnell, Iowa, September 18, from heart disease.

William J. Judd, M.D. St. Louis Medical College, 1861, died at his home in Henderson, N. C., September 7.

William W. Gray, M.D. Cincinnati, 1863, died at his home in Pasadena, Cal., September 21, aged 70.

Joseph H. Holloway, M.D. Cincinnati, 1878, died at his home in Auburn, Ind., September 12.

Book Notices

MANUAL [illegible] J. Rogues de Fursac, M.D., Formerly Chie[illegible]lical Faculty of Paris. Authorized Transl[illegible] by A. J. Rosanoff, M.D., Junior Assistant [illegible] Hospital, Kings Park, N. Y. Edited by [illegible] rofessor of Diseases of the Mind and Nervo[illegible]ew York Postgraduate Medical School. F[illegible] Pp. 352. Price, $2.50. New York: Joh[illegible]

To put all of modern psychiatry into a little manual of 350 pages is obviously impossible. A reasonably full handbook would have to be at least twice as large. But given this limit, it is hard to see how the author could have done better. He surely has the art of the text-book writer. That is, he has that peculiar sense of proportion which enables him to select from the immense mass of the known what is essential and what is important, and he knows how to present his matter simply and clearly. The defects of the work are those inherent in brevity; First, paucity of detail and lack of exceptions; second, absence of adequate discussion of unsettled questions (and in psychiatry their name is legion); third, unwarranted dogmatism of statement or want of qualification.

These defects granted, the book is a thoroughly commendable one; an excellent text-book for students and guide for practitioners who do not know a great deal and do not aspire to know a great deal of mental disease. The style is so simple and direct that the work is well adapted for the use of psychologists, lawyers, teachers and other non-medical persons who may have occasion to learn something of insanity. Even for those already well versed in psychiatry, it is far from being a barren manual. It is up to date, and contains especially good presentations of three subjects now of particular interest in the world of psychopathy: dementia præcox, Korsakoff's (or Korsakow's) psychosis and manic-depressive insanity. And this brings us to the question of classification. Presumably no review of a work on insanity is complete without a criticism of the author's classification. And, frankly, we do not agree with the author. The latter follows Kraepelin, but has chosen to do so with modifications which appear to us not always happy. However, in the text, he several times begs the question and, besides, for the practitioner the matter of classification is far from being the most important.

The book is divided into two parts: general psychiatry (120 pages) and special psychiatry (216 pages). There is an appendix containing an excellent guiding scheme for the investigation of insane patients (6 pages). Part I, embodying etiology, symptomatology, examination of patients and general therapeutics, is as good as anything we have seen on the subject. Hallucinations, delusions, amnesia, disorders of reaction, etc., are treated very briefly, but very clearly. In Part II the descriptions of disease are good. In addition to the chapters on dementia præcox, Korsakoff's psychosis and manic-depressive insanity already mentioned, that on senile dementia is particularly satisfactory. Diagnosis and prognosis receive rather scant space, and in many instances the consideration of treatment is too meager to be useful. Throughout the second part a laudable effort is made to supplement the brevity of the text with bibliographic references, and these are well chosen and sufficiently numerous. Unfortunately for English readers, they are all French and German. It would seem to us that the editor might easily have supplied, what really should have been in the original, some references to British and American literature. In fact, we have been unable to discover any *raison d'etre* of the aforesaid editor except to cumber the title page with the inverted pyramid of his numerous titles. If he really contributed to the proper construction of this translation of a firstrate book, we should be made aware of the fact. Otherwise, many will assume that he is introduced for purely ornamental purposes.

The translation has been well done, although there is room here and there for a bit of discussion. For instance, the literal translation of the word *moral(e)* is sure to mislead some readers unacquainted with French. To say that the obstacles to the home treatment of the insane are "both material and moral" is not an exact statement. The "moral pain" of the melancholiac has no necessary relation to right and wrong. The book is well printed on good paper.

ABDOMINAL PAIN. Its Causes and Clinical Significance. By A. Ernest Maylard, M.B., B.S., London. Cloth. Pp. 304. Price, $2.50 net. Philadelphia: P. Blakiston's Sons & Co. 1905.

This is a most interesting monograph on the diagnosis of diseases within the abdomen. Pain is the chief symptom in most of these diseases and therefore has been considered in great detail by this author. The early chapters in the book are devoted to a consideration of the distribution of nerves to the organs within the abdomen and to the walls of the abdomen, and to the general causes of pain.

Pain in affections of the alimentary tract, liver, bile ducts, pancreas, urinary system, reproductive organs, spleen, aorta, etc., is treated of in succeeding chapters. The last chapters are devoted to a regional pain and will be of much assistance to the practitioner in locating the organ which gives rise to pain. The subject of differential diagnosis is fully discussed. Although pain is the chief symptom all others are considered. This book brings together in convenient form our knowledge of this subject. We cannot agree with the author that his last chapters on the performance of laparotomy are in place. He pleads that "so much has been gleaned from abdominal surgery in recent years, I did not think it would be out of place to conclude with a chapter or two on the performance of laparotomy." These chapters are not in place. However, they do not lessen the value of the book which we gladly commend to our readers.

SYSTEM [illegible] THERAPEUTICS, Under the General Editorial Cha[illegible]n. Vol. [illegible]nd Physical [illegible] Massage [illegible] K. Mitchell, M.D., and Physical Education [illegible] by L. H. Gulick, M.D. Pp. 420. With 299 [illegible] Rest, Mental Therapeutics, Suggestion, by F. X. Dercum, M.D., Ph.D. Pp. 33[illegible]y J. McFarland; Organotherapy, O. T[illegible]m, Thorum and Radioactivity, by S[illegible] Applications, [illegible] the Principles [illegible] logic Therapeutics by the Editor and an [illegible] plete System of Eleven Volumes. Illustrated. Pp. 388. Price, $2.50 per volume. Philadelphia: P. Blakiston's Son & Co. 1905.

On the whole it must be said that this ambitious undertaking has been brought to a successful issue. The three volumes mentioned can not but prove valuable additions to the physician's library. The subjects considered are presented in an interesting and instructive manner. The editor's discussion of the principles of physiologic therapeutics is clear and thoughtful and should be read by all physicians who wish to substitute rationalism for blind empiricism in their treatment of disease. Probably the introduction of such words as toxolysin and toxolysis for antitoxin and its action on toxin must be regarded as rather ill-chosen innovations because they do not express correctly the nature and actions of antitoxin. The whole system merits wide distribution because it certainly represents a strong and successful effort to give an exposition of the very important methods of treatment, preventive and curative, now available other than drug giving.

DIETETICS FOR NURSES. By J. Friedenwald, M.D., and J. Ruhräh, M.D. Cloth. Pp. 363. Price, $1.50 net. Philadelphia: W. B. Saunders & Co. 1905.

In this work the essential points in dietetics are given in a clear and concise way. The introductory chapters on the chemistry and physiology of digestion are well and intelligibly written. The chapters on "Various Factors in Their Bearing on Diet" and "The Feeding of Infants and Children" are very practical, the formulas for modifying milk being especially so. The diet in special diseases is reviewed in some detail and the book concludes with recipes for many appetizing dishes. The book should be of value to physicians as well as to nurses.

A REFERENCE HANDBOOK FOR NURSES. By Amanda K. Beck of Chicago. Bound in Flexible Morocco. Pp. 150. Price, $1.25 net. Philadelphia: W. B. Saunders & Co. 1905.

The notes taken by a student while in school or college may be invaluable to him but of little use to anyone else, and the same rule applies to the notes taken by a probationer or undergraduate nurse while in the hospital training school. It has been said that well trained nurses never diagnose and never prescribe, but Miss Beck's book implies that they do both. It contains a chapter on "Miscellaneous Formulæ" in which the first formula given is for "Semmola's mixture" "to eliminate the kidneys." We trust that Miss Beck seldom finds it necessary to eliminate these useful organs. Many of the formulas given are practical and should be helpful in preparing the various "stock solutions" of disinfectants. We thought that the onion poultice mentioned on page 47 was a thing of the past. The chapters on general nursing are good, and that on diet is perhaps the best in the book; it contains recipes for many appetizing dishes to tempt the capricious appetite of a sick or convalescent patient.

Miscellany

Lumbar Puncture in Treatment of Uremia.—Prof. G. Carrière of Lille writes to the *Archives Gen. de Méd.* of September 12 that he found lumbar puncture actually a lifesaving measure in two cases of uremia. It failed to show any benefit in four cases, but was useful in two others, and is liable to be beneficial in all cases. It acts by reducing the pressure of the cerebrospinal fluid and reducing the tendency to edema, while it removes the poisonous fluid that is irritating the cells of the cortex. He found that the cerebrospinal fluid in cases of nervous uremia was invariably hypertoxic. In some other cases the trouble was evidently due to compression, and in others to edema of the brain, all being conditions liable to benefit by lumbar puncture.

Carbolic-Acid Burn.—Commenting on the use of alcohol in burns from carbolic acid, Dr. F. P. Minton, East Toledo, Ohio, refers to the length of time which elapsed between the occurrence of the injury and the application of the alcohol in the case reported by Dr. T. J. Swisher, Rawlins, Wyo., in The Journal, Sept. 2, 1905, page 717, and reports an interesting case which came under his observation. In dressing an extensive wound of the face, after the stitches were removed, a 95 per cent. solution of carbolic acid was accidentally poured on the wound instead of peroxid of hydrogen. The mistake was discovered almost instantly, and as no alcohol was at hand, the surgeon washed off the wound with fluid extract of ergot, tincture of opium, paregoric and other preparations in his valise containing alcohol. He then applied a dressing of antiseptic cotton saturated with whisky. The results were entirely satisfactory, and the patient never knew of the accident.

"The Feminine Peril."—Lutaud has a breezy editorial in the last *Jour. de Méd. de Paris* on the way in which women are supplanting men in the business world. No law, no human force can stop the progress of this revolution, he says, which he regards as of much more moment than a possible "yellow peril." Within a few years, he remarks, the conditions of social life will have been revolutionized. The directing force will be inevitably feminine, and men, having nothing more than the superiority conferred by greater physical strength, will be utilized only in rough work requiring such strength. He adds that the female natality is increasing and the female mortality rate is diminishing, the latter due to the absence of the vices and excesses which are the prerogative of "the superior animal," man. Fifty years from now the healthy, vigorous man will find no outlet for his faculties except in the rare manual professions which require physical strength. All of which is very funny.

The First Postmortem in Montreal.—According to the *Montreal Medical Journal* there is to be found in the description of "Hakluyt's Voyages," of the travels of Jacques Cartier, the following record of the earliest reported autopsy performed in that city. It took place in Montreal, then known as Hochelaga, in the winter of 1535, when many sailors died of an epidemic disease. "That day Philip Rougement, born in Ambroise, died, being 22 yeeres olde and because the sickness was to us unknowen, our Captaine caused him to be ripped to see if by any means possible we might know what it was, and so seeke meanes to save and preserve the rest of the company. He was found to have his heart white, but rotten, and more than a quart of red water about it; his liver was indifferent faire, but his lungs black and mortified, his blood was altogither shrunke about the heart, so that when he was opened great quantitie of rotten blood issued out from about his heart; his milt (spleen, Ed.) toward the back was somewhat perished, rough as if it had bene rubbed against a stone. Moreover, because one of his thighs was very blacke without, it was opened, but within it was whole and sound, that done as well as we could, he was buried."

Growing Youth, Health and the Nervous System.—No subject is of more importance than the mental, moral and physical training of the child and growing youth of our land. History indicates that body, mind and morals are the trinity of essentials for the welfare of individuals and nations. This being the case, and viewing facts from a utilitarian standpoint alone, it behooves physicians, parents and educators to face the matter of parenthood in its broadest aspects. The child is being overworked by present day methods of education. The rapid advances in all avenues of thought and science to-day, and the failure to remember that the human body has not changed materially the while is the basic reason for the degeneration of our methods of education and the defeat of our aims for an ideal higher growth of the race. Time has come to call a halt. Ways and means of preventing overwrought nervous systems must come if we are to lead the cause of advance of humanity. Let us work it out carefuly and at once.—*Wisconsin Medical Journal.*

Medical Education in Itlay.—Carrara of Turin contributes an interesting sketch of the conditions of medical instruction and practice in Italy to the *Deutsche med. Wochft* of June 8. He states that there are 17 state universities in Italy, with 4 colleges, 3 independent universities, 3 obstetric training schools, and other colleges, a total of 30 higher institutions of learning. Fifteen of the above universities have a medical department. All are supported by the state except the three independents, which are maintained by the community. This scattering of the funds that might support handsomely a few higher institutions among such a number of small ones, is deplored by all writers. In Germany the state expenditures for its 22 universities and colleges are $5,000,000, while Italy has only $1,600,000 to distribute among its 17. The number of college-bred men to 100,000 inhabitants was, in 1891, in Germany, 48, in France 42, in Denmark 45, in Austria 55 and in Italy 51, while the proportion in Italy is constantly increasing. The number of physicians to the 100,000 inhabitants is also increasing, being 66 in 1898 and still higher now. Milan has recently founded an institute for postgraduate work in gynecology, occupation affections and communicable diseases. The state has appropriated nearly $70,000 a year for the support of this postgraduate school.

Medical Science in Turkey Under the Present Sultan.—The *Lancet* in an editorial calls attention to the little known fact that the Sultan of Turkey has done much for his subjects in a medical and hygienic way, and states that he has always been eager to let his people benefit as much as possible by the latest discoveries of science. He has established a large number of charitable institutions in his dominions, and fountains of cool well water, which are such a boon in a distinctly warm country like Turkey, have been established at the expense of his private purse. In Constantinople every district in the city has such a fountain, which supplies drinkable water free of expense. In that city, too, asylums, lazarets and hospitals of various descriptions, receiving the personal endowments of the Sultan, keep their doors open for sufferers of every nation and give them free treatment. The Sultan is said to be especially interested in sick children, and for them has established the Hamidié Hospital, a first-class institution equipped with all the requirements of modern science. All the best medical men in the country are engaged in the service of this hospital, and they are assisted by a staff of German nurses. The large leper hospital on the Asiatic side of the Bosphorus also receives the attention of the Sultan, and a place of refuge for the poor and aged and an asylum for the insane have been created and are sustained by his large contributions. Through his initiative also Constantinople possesses a large medical school with an efficient staff of professors and lecturers. The Sultan is said to take an interest in all medical congresses. Recently he has set on foot a movement to create in Constantinople an establishment for the deaf and dumb. These things, says the *Lancet*, seem to prove that the popular estimate of the Sultan of Turkey is not wholly justified.

The Medical Reprint.—There is one form of medical literature which is particularly deserving of discontinuance. There was never much that could be urged as justification for sending out thousands of reprints of an article already published and read in a reputable medical journal. Undoubtedly the one thing which has served to keep the custom alive is the fact that such reprints are supposed to be highly valuable as a means of advertising the ability or the accomplishments of the man by whom they are sent out. The reprint occupies the same position in the field of medical advertising that the hand-bill does in the more common commercial walks. If any merchant could afford to pay for the amount of space for "pure reading matter" given the usual contributor to a medical journal for his article, he would not even dream that it was necessary to follow this excellent method of advertising by the cheaper and much less effective plan of reprinting his "pure reading matter" in the form of hand-bills and distributing them to the populace. For the men who have the handling of medical literature—publishers and librarians—the reprint is useless or worse. There are but few libraries in which any serious effort is made to catalogue or systematically care for the medical reprint. In nine cases out of ten the reprint is simply a duplication of what the library already possesses in some of its periodicals—to give time and labor to the care of duplicate matter is no part of the modern way of doing things. The day of the reprint is waning and it is to be expected as well as hoped that this particular method of overloading our mails and burdening our shelves will soon cease to be fashionable.—*Western Medical Review.*

The County Medical Society.—Physicians get together little enough, and do not really know one another except through the report of friends or patients. A closer intimacy between physicians would clear away much of the malicious gossip that passes as medical news. The social side of the country physician needs stimulating. He is too apt to depend on his practice and environment for his idea of the life of a physician. Unless he is ready and willing to meet his brother practitioner in a friendly spirit, and to exercise his mental faculties in medical and non-medical topics, he soon drops into a rut, from which there is no escape. His ideas narrow until he sees nothing but a thin and wavering medical line from which he dares not deviate. This brings discontent, discouragement, and failures, and the blame is frequently placed on innocent shoulders, when it actually should be borne by the physician himself. Every county society is a medical index, and insures to a greater or a lesser degree the standing of each member. Each meeting, however trite the papers and discussions, should contain some suggestion that can be profitably carried home by the members. True, some meetings are tiresome, but the inertia is due to the mental inertia of the members of the society, hence the blame is distributed over the entire society. The presiding officer or the committee in charge of the program are usually responsible for the character of the meeting. No medical society is a success unless its officers are determined to do their part of the work. There is no excuse for a poor medical society, particularly if it has had a few "experience" meetings. The fault can be easily located, and as easily remedied. Even in the small county societies the exhibition of a specimen with a clinical report of a case will call out discussion.

Physicians are reserved, shy, or embarrassed in medical societies. They hesitate to express their views for fear of exposing their lack of knowledge or for fear of criticism. It is better to attack a subject openly rather than let some loose statement go unchallenged. It is better to attempt to talk to the point, even though the speaker has opposite views from the essayist, rather than hide one's light under the cloak of indifference. The activity, interest, and competition is what makes the large county society or state organization a success. If you feel that your brother physician is too aggressive, display some aggression yourself; if you think the American Medical Association is conducted for the benefit of a few, get into line and be one of the pushers. Push is a force that is wholesome, and it is not flagrant advertising. Be modest if you please, but show what you know. If you know but little, you will learn by the criticism of others. The man who expects to succeed does not fear competition; he makes himself heard, and his reward is commensurate with his worth. The evil of many medical societies is the "knocking" proclivities of its members. Petty jealousies have no place, and gain no rewards, in medical societies. The best men do the best work, and the grumbler admits his failure. Medical men should come together for their own good, their social advancement, mental athletics, fraternalism, comparison of views, vigorous discussion, the recital of experiences, and exhibitions of their work. A clinic or a pathologic exhibit or the record of a case is sufficient reason for the congregating of medical men. A mediocre paper containing matter of common knowledge is usually a bore, but who knows but that one man may profit by it? A medical society without life or advancement should be rejuvenated by the injection of new blood into the committee, and the new material will awaken interest in spite of the old backsliders.—*Northwestern Lancet.*

Satisfy Minimum Requirements.—The following letter of a professor of clinical medicine speaks for itself, and more truly perhaps than the author intended. He says:

> In order to sustain the excellent standing we are honored with by your board, we ask that you kindly furnish us with a copy of your latest schedules of minimum requirements for medical colleges in order that our next announcement may conform to the same.

To conform to *minimum* requirements is a modest ambition, and prevalent in all trades. In the trade of medical schooling the minimum requirements are easy enough, but their attainment is difficult for a good majority of medical schools. A few years ago the minimum requirements were easy enough to be contemptible, but that phase is passing. In another year or two the minimum requirements will be respectable, and their attainment will be for many schools impossible. Eventually it will be an honorable ambition to conform to the minimum requirements. That time indeed is coming all too swiftly, but it cannot be delayed. In medical education the improvement which has become possible through large endowments will no more falter in its advance than the earth in its orbit, and in that advance the doom of the small proprietary schools is inexorably sealed. Especially pitiable is the case of those who have misread the signs of the times and cast their lot with the purely commercial schools in an unavailing effort to slow the wheels of progress. More than one unendowed school having an honorable history, a competent faculty and a body of influential alumni, has foolishly allowed the gap ahead to widen and the gap behind to close, until they are lost in a ruck of disreputables marked for slaughter. Far different is the case of those few unendowed schools whose faculties early realized that their only salvation was to follow pace. These furnish the most inspiring spectacle in the field of medical education. It is a pity that any of them should be utterly spent in the unequal race. Some of them, and these are wise, have combined forces. This expedient is cruel, but not more cruel than the spur of necessity. Many men of weight in the medical affairs of the present generation will probably outlive the schools which launched them on honorable careers. The declining influence of some proprietary schools must be a matter of serious concern to their alumni, and an active intervention might in some instances restore such schools to enduring usefulness.—*American Medicine.*

Queries and Minor Notes

Anonymous Communications will not be noticed. Queries for this column must be accompanied by the writer's name and address, but the request of the writer not to publish name or address will be faithfully observed.

FORMULA FOR BLOOD SOLVENTS.

Manchester, N. H., Sept. 18, 1905.

To the Editor:—Will you kindly send me formulas for blood solvents that will keep the blood from coagulating in the veins during the process of embalming dead bodies? X. Z.

Answer.—The injection of albumose solutions, e. g., Witte's peptone, into the veins of the living animal, prevents the coagulation of the blood; an effusion of the mouth of the officinal leach has a similar effect. *Potassium oxalate* when mixed with blood in a concentration of 0.1 per cent. prevents coagulation by combining with the soluble calcium salts. It is probable that concentrated solutions of other salts, as sodium or magnesium sulphate would have a similar effect, if used in large amounts. After death has occurred, it is difficult to obtain a uniform mixture of these substances with the blood, and they can be used to prevent clotting, but not to dissolve clots already formed. It is probable that they would be most effective when used to wash the blood out of the vessels before postmortem clotting has set in.

State Boards of Registration

COMING EXAMINATIONS.

Regular Board of Medical Examiners of Georgia, The Capitol, Atlanta, October 9. Secretary, F. D. Paterson, Cuthbert.

Michigan State Board of Registration in Medicine, Capitol Building, Lansing, October 10. Secretary, B. D. Harison, Sault Ste. Marie.

State Medical Board of the Arkansas Medical Society, Little Rock, October 10. Secretary, J. P. Runyan, Little Rock.

Board of Medical Examiners of State of Florida, Jacksonville, Oct. 10-11. Secretary J. D. Fernandez, Jacksonville.

Kansas State Board of Medical Registration and Examination, State House, Topeka, October 10-11. Secretary, G. F. Johnston, Lakin.

State Board of Medical Registration of Vermont, Y. M. C. A. Hall, Burlington, October 10-12. Secretary, W. S. Nay, Underhill.

Board of Medical Supervisors of Washington, D. C., Washington, D. C., October 12. Secretary, W. C. Woodward, Washington, D. C.

Board of Medical Examiners of State of Texas, San Antonio, October 17. Secretary, T. T. Jackson, San Antonio.

State Board of Medical Examiners of New Jersey, Trenton, October 17-18. Secretary, E. L. B. Godfrey, Camden.

State Board of Health of Illinois, The Great Northern Hotel, Chicago, October 18. Secretary, J. A. Egan, Springfield.

Louisiana State Board, New Orleans, October 20-21. Secretary, F. A. Larue, New Orleans.

State Board of Heath of Kentucky, Louisville, October 24. Secretary, J. N. McCormack, Bowling Green.

Virginia June Report.—Dr. R. S. Martin, secretary of the Medical Examining Board of Virginia, reports the written examination held in Richmond, June 20-24, 1905. The number of subjects examined in was 9; total number of questions asked, 75; percentage required to pass, 75. The total number of persons examined was 206, of whom 107 passed and 33 failed; 62 non-graduates took partial examination, 4 incomplete. Two candidates presented certificates from reciprocating boards and were granted licenses to practice, without examination. After oral examinations licenses were granted to four individuals who had been in active practice for five years or more, as is the custom of the board. No percentages were assigned. Representatives of the following colleges passed the examination:

Nebraska August Report.—Dr. George H. Brash, secretary of the Nebraska State Board of Health, reports the written examination held at Lincoln, Aug. 9-10, 1905. The number of subjects examined in was 8; total number of questions asked, 80; percentage required to pass, 75. The total number of candidates examined was 18, of whom 9 passed and 9 failed. Representatives of the following colleges passed:

PASSED.

College.	Year. Grad.	Per Cent.
Lincoln Med. Coll*	(1905)	75.25
Barnes Med. Coll*	(1905)	81.5
Northwestern University	(1905)	88.3, 90.75, 92.8

*Second examination.

California August Report.—Dr. Charles L. Tisdale, secretary of the State Board of Medical Examiners of California, reports the written examination held at San Francisco, August 15-17, 1905. The number of subjects examined in was 9; total number of questions asked, 90; percentage required to pass, 75. Forty-two candidates were examined, of whom 20 passed and 22 failed. Representatives of the following colleges passed:

PASSED.

College.	Year. Grad.	Per Cent.
Johns Hopkins University, Baltimore	(1905)	83.2
University of California	(1905)	80, 84.4

The Public Service

Army Changes.

Memorandum of changes of stations and duties of medical officers, U. S. Army, for the week ending Sept. 30, 1905:

Arthur, Wm. H., McCaw, W. D., Glennan, James D., surgeons, appointed members of a board of officers, to meet at the Army Medical Museum Building, Washington, D. C., for the examination of such officers of the Medical Department as may be ordered before it to determine their fitness for promotion or advancement.

Bratton, Thomas S., asst.-surgeon, ordered to report to Major William H. Arthur, surgeon, president, examining board, Washington, D. C., on Oct. 10, 1905, for examination to determine his fitness for promotion.

Connor, C. H., asst.-surgeon, relieved from duty on the transport *Sheridan*, and will proceed without delay to Fort Stevens, Ore., for duty at that post.

Bratton, Thomas S., asst.-surgeon, granted seven days' leave of absence.

Marrow, Charles E., asst.-surgeon, ordered to temporary duty in charge of office of attending surgeon and examiner of recruits, Chicago, Ill., during absence of Captain Bratton.

Woodbury, F. T., asst.-surgeon, granted thirty days' leave of absence.

Wilson, James S., asst.-surgeon, left Fort Oglethorpe, Ga., on twenty-one days' leave of absence.

Truby, A. E., asst.-surgeon, reports departure from detached duty at Fort Leavenworth, Kan., on thirty days' leave of absence.

Reynolds, Charles R., asst.-surgeon, ordered to report in person on October 5, to Major William H. Arthur, surgeon, president of the examining board at the Army Medical Museum building, Washington, D. C., for examination to determine his fitness for advancement.

The following asst.-surgeons will report in person on the dates specified, to Lieut. Col. George H. Torney, deputy surgeon general, president, examining board at Army General Hospital, Presidio, San Francisco, for examination to determine their fitness for promotion: Baker, Frank C., October 31; Vose, William E., October 31; Woodbury, Frank T., October 31; Dale, F. A., November 28; Edwards, James F., November 28; Chidester, Walter C., November 28; Williams, Allie W., December 29.

Shortlidge, E. D., asst.-surgeon, leave of absence extended thirty days.

Howard, D. C., asst.-surgeon, ordered to report in person Oct. 10, 1905, to Major William H. Arthur, surgeon, president, examining board, Washington, D. C., for examination to determine his fitness for promotion.

Reagles, James, contract surgeon, granted leave of absence for one month, with permission to apply for an extension of one month.

Whinnery, Jean C., dental surgeon, left Fort St. Michael, Alaska, and arrived at Fort Davis, Alaska, for temporary duty.

McAlister, John A., dental surgeon, arrived at Presidio of Monterey, Cal., for duty.

Newlove, George, contract surgeon, left San Francisco, with squadron of the Twelfth Cavalry, for Fort Oglethorpe, Ga.

de Quevedo, Luis G., contract surgeon, left San Juan, P. R., and arrived at Cayey, P. R., for temporary duty.

Thorp, Charles W., contract surgeon, ordered from Fort Ethan Allen, to Plattsburg, Barracks, N. Y., for temporary duty.

Greenwell, Samuel A., contract surgeon, left Fort Barrancas, Fla., on leave of absence.

Navy Changes.

Thompson, J. C., P. A. surgeon, ordered to the naval recruiting station, Providence, R. I.

White, E. C., Reed, T. W., Reed, E. U., Old, E. H. H., McConnon, G. H., asst.-surgeons, appointed assist.-surgeons with rank of lieutenant (junior grade), from Sept. 21, 1905.

Wedekind von, L. L. surgeon, detached from the *Lancaster* and ordered to the navy recruiting rendezvous, Chicago.

Richards, T. W., surgeon, detached from the navy recruiting rendezvous, Baltimore, and granted leave for thirty days.

De Valin, C. M., surgeon, detached from the naval hospital, Philadelphia, and ordered to the Lancaster.

Peck, A. E., P. A. surgeon, detached from the *Bennington* and ordered to the *Concord*.

Angeny, G. L., P. A. surgeon, ordered to the naval hospital, Philadelphia.

Moore, J. M., P. A. surgeon, detached from the navy recruiting rendezvous, Chicago, and directed to wait orders.

Brown, E. M., asst.-surgeon, detached from the navy yard, Mare Island, Cal., and ordered to the Naval Medical School, Washington, D. C.

Geiger, A. J., asst.-surgeon, ordered to the navy yard, Mare Island.

Hull, H. F., asst.-surgeon, detached from the Naval Hospital, Philadelphia, and ordered to the Naval Academy.

Heiner, R. G., asst.-surgeon, detached from the navy yard, Washington, D. C., and ordered to the *Scorpion*.

Richardson, F. A., acting asst.-surgeon, detached from the *Scorpion* and ordered to the navy recruiting rendezvous, Baltimore, Md.

Field, J. G., surgeon, detached from the *Solace* and ordered to the *Celtic*.

Spear, R., surgeon, detached from special duty at St. Petersburg, Russia, and ordered to the Asiatic station.

McConnon, C. H., Reed, E. U., Reed, T. W., White, E. C., and Old, E. H. H., asst.-surgeons, ordered to Washington, D. C., for course of instruction at the Naval Medical School.

Oman, C. M., asst.-surgeon, ordered to the Naval Hospital, Norfolk, Va.

Health Reports.

The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon General, Public Health and Marine-Hospital Service, during the period from September 16 to 29:

SMALLPOX—UNITED STATES

California: San Francisco, Sept. 2-16, 2 cases.

District of Columbia: Washington, Sept. 8-16, 1 death.

Florida: Jacksonville, Sept. 8-16, 1 case.

Illinois: Galesburg, Sept. 16-23, 1 case.

Minnesota: Four counties, July 31-Aug. 14, 28 cases; six counties, Aug. 14-21, 26 cases; three counties, Aug. 21-28, 6 cases; two counties, Aug. 28-Sept. 11, 8 cases.

Ohio: Cincinnati: Sept. 1-8, 4 cases, Sept. 15-22, 3 cases.

Pennsylvania: Allegheny, Sept. 2-9, 1 case; York, Sept. 8-16, 7 cases.

Wisconsin: Appleton, Sept. 16-23, 4 cases.

SMALLPOX—FOREIGN.

Africa: Cape Town, July 29-August 5, 5 cases.

Argentina: Buenos Ayres, June 1-30, 34 deaths.

Brazil: Pernambuco, July 1-31, 393 deaths; Rio de Janeiro, Ar[illegible], 3 deaths.

China: Niuchwang, Aug. 5, 1 case.

Ecuador: Guayaquil, Aug. 22-Sept. 5, 7 deaths.

France: Paris, Aug. 27-Sept. 9, 35 cases, 5 deaths.

Great Britain: Liverpool, Sept. 9-16, 1 case, imported; Plymouth, Sept. 2-9, 9 cases.

India: Bombay, Aug. 9-15, 1 death; Calcutta, Aug. 5-26, 4 deaths; Karachi, Aug. 6-13, 1 case, 1 death; Madras, Aug. 5-18, 14 deaths.

Italy: General, Aug. 18-24, 14 cases; Aug. 31-Sept. 7, 7 cases; Catania, Aug. 31-Sept. 7, 2 cases; Messina, Aug. 12-19, 4 cases, 4 deaths.

Russia: Moscow, Aug. 12-Sept. 2, 15 cases, 6 deaths; Odessa, Aug. 19-Sept. 9, 15 cases, 3 deaths; St. Petersburg, Aug. 19-26, 3 cases, 1 death.

Turkey: Constantinople, Aug. 28-Sept. 10, 3 deaths.

YELLOW FEVER—UNITED STATES.

Florida: Pensacola. Aug. 29-Sept. 25, 101 cases, 12 deaths.

Kentucky: Lexington, Sept. 17, 2 refugees.

Louisiana: Ascension Parish, to Sept. 23, 70 cases, 3 deaths; Assumption Parish, to Sept. 25, 30 cases; Avoyelles Parish, to Sept. 25, 10 cases, 2 deaths; East Baton Rouge Parish, to Sept. 24, 5 cases; East Carrol Parish, to Sept. 25, 264 cases, 31 deaths; Iberville Parish, to Sept. 13, 16 cases, 3 deaths; Jefferson Parish, to Sept. 26, 342 cases, 43 deaths; Lafayette Parish, to Sept. 26, 8 cases; La Fourche Parish, to Sept. 24, 379 cases, 47 deaths; Madison Parish, to Sept. 26, 261 cases, 16 deaths; Morehouse Parish, to Sept. 18, 1 case, 1 death; Natchitoches Parish, to Sept. 20, 76 cases, 5 deaths; Orleans Parish, New Orleans, July 21-Sept. 27, 2,907 cases, 378 deaths; Plaquemines Parish, to Sept. 23, 57 cases, 8 deaths; Rapides Parish, to Sept. 25, 20 cases; St. Bernard Parish, to Sept. 25, 61 cases, 3 deaths; St. Charles Parish, to Sept. 20, 114 cases, 16 deaths; St. John the Baptist Parish, to Sept. 26, 150 cases, 14 deaths; St. Mary Parish, to Sept. 25, 672 cases, 26 deaths; Tangipahoa Parish, Sept. 17, 2 cases; Tensas Parish, to Sept. 23, 4 cases; Terrebonne Parish, to Sept. 23, 229 cases, 10 deaths.

Mississippi: Enoka: Sept. 15, 1 case; Gulfport, Aug. 15 Sept. 25, 75 cases, 1 death; Gulf Quarantine, July 22 Sept. 2, 61 cases, 1 death; Hamburg, Sept. 15-25, 23 cases, 4 deaths; Handsboro, Sept. 17-24, 3 cases; Harriston, to Sept. 25, 2 cases; Mississippi City, Aug. 22-Sept. 25, 50 cases; Natchez, to Sept. 25, 35 cases; Roxie (vicinity of), to Sept. 25, 5 cases; Soria, Sept. 15, 1 case; Vicksburg, Aug. 30-Sept. 25, 57 cases, 7 deaths.

YELLOW FEVER—FOREIGN.

Brazil: Rio de Janeiro, Aug. 20-27, 5 cases.

Guatemala: Tocura, Aug. 23, present.

Honduras: Puerto Cortez, Aug. 29-Sept. 5, 2 cases; San Pero, Aug. 20-30, 4 cases.

Mexico: Coatzacoalcos, Sept. 10-15, 1 case; Merida, Sept. 17, 1 case; Tehuantepec, Sept. 3-9, 1 death; Tezonapa, Sept. 3-15, 2 cases, 2 deaths; Vera Cruz, Sept. 3-9, 4 cases, 1 death.

Nicaragua: San Francisco, Aug. 27, 2 deaths.

Panama: Bocas del Toro, Sept. 9, 5 removed from steamship *Preston;* Panama, Aug. 27-Sept. 9, 6 cases, 1 death.

CHOLERA.

Germany: Hamburg, Aug. 26-Sept. 6, 3 cases, 1 death; Posen-Stettin, Sept. 19, 1 death.

West Prussia: Vistula District, to Sept. 7, 105 cases, 32 deaths.

India: Bombay, Aug. 8-15, 1 death; Calcutta, Aug. 5-26, 36 deaths; Madras, Aug. 5-25, 1,313 deaths.

PLAGUE.

Africa: Cape Colony, Port Elizabeth, Aug. 12-19, 1 case, 1 death.

Brazil: Rio de Janeiro, Aug. 20-27, 9 cases, 2 deaths.

Chili: Taltal, Aug. 30, 3 cases.

India: Bombay, Aug. 8-29, 139 deaths; Calcutta, Aug. 5-26, 34 deaths; General, July 29 Aug. 5, 1,445 cases, 1,054 deaths; Karachi, Aug. 6-27, 29 cases, 20 deaths.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Eighteenth Annual Meeting, held at New York,
Sept. 19-21, 1905.

(Continued from page 1022.)

The After Management of Abdominal Sections.

Dr. Walter B. Chase, Brooklyn, N. Y., said that, in reviewing his personal experience, he is led to the conclusion that the principal and by far the most frequent condition after laparotomy requiring treatment is flatulence. The accumulation of gas in the intestinal tract is present, to a greater or less extent, in a majority of cases. The principal causes are reversed peristalsis, intestinal paresis, and the effect of the anesthetic itself. He seldom gives anodynes, except in conditions of pain, making a possible exception in cases when peritonitis was present prior to the operation, or other structures involved in the operation were so friable that peristalsis should be prevented for a time, or in cases following intestinal anastomosis. Its administration for the relief of pain is admissible and perhaps mandatory. It is a matter of much moment what anodyne is selected. Ordinarily he uses codein hypodermically in doses of gr. ¼ to ½, or more, if required. While its power to relieve pain and check peristalsis is much inferior to that of morphin, its lesser disturbance of the nervous system, checking of secretion, and tendency to undue constipation makes it an agent of great value. It is imperative that a reliable preparation be used. In troublesome cases of continued nausea the administration of small doses of cocain, gr. 1/10 to 1/12, exercises a salutary sedative influence on the nerves supplying the stomach, and is attended with happy results. Either the nausea or flatulence, or both, may disappear in a few hours after operation.

Among the newer remedies for the relief of intestinal paresis is the alkaloid of the calabar bean. Salicylate of physostigmin, given in doses of gr. 1/100 to 1/50, or even more, hypodermatically, repeated once in four hours, seems to induce a powerful contraction of the circular fiber of the intestinal tract. The diet of patients after abdominal section calls for the greatest circumspection, always following the rule that nourishment, taken per os, before the stomach retains or digests it, is positively harmful. When shock is profound, minute doses of morphin sulphate are among the most powerful stimulants, and superior to most for prompt and sustained effect. The author discussed at length the importance of bodily temperature and position of patient after laparotomy.

Trivial Uterine Causes of Severe Gastric Disturbances.

Dr. Francis Reder, St. Louis, said that, during the last two years, eight patients came under his observation, six of whom presented a train of symptoms that would ordinarily be grouped as those of hysteria or neurasthenia, moderately severe in character, the remaining two patients being free from any such pronounced neuropathic phenomena, and some in fairly good health, with the exception that their stomachs were weak. The pelvic organs, on examination, gave evidence of disease, and, although the examination did not reveal anything of a serious nature, yet local minor surgical procedures afforded relief.

In the cases cited by the author, it was a surgical procedure that anticipated the pathologic conditions. He said to wait for pathologic conditions to give evidence of their existence by more pronounced local symptoms in gynecologic disease, where there is a marked reflex neurosis, would be to invite secondary conditions that might prove of a very grave nature.

DISCUSSION.

Dr. Rufus B. Hall thought the cases reported by the essayist had pathologic conditions sufficiently marked to justify operation, regardless of their neurotic condition. To cure nervous patients, it is sometimes necessary to remove every obstacle in the way of perfect health physically. He is convinced that if many of these cases had not been operated on their condition would have become worse, a more grave pathology would have resulted later, and it would have been more trying for the patients, thus making the surgery more difficult and harder for the patients to recover from the operation.

Dr. X. O. Werder, Pittsburg, is not enthusiastic about operating on neurotic patients, as the results are not usually good, and he feared the essayist would have some of the patients on whom he had operated return in a few months with the same symptoms having recurred.

Prolapsus Uteri and Its Treatment.

Dr. Herman E. Hayd, Buffalo, N. Y., briefly spoke of the various conditions which contribute to the production of prolapsus uteri, and then immediately discussed its treatment by surgical means only. His operative treatment is carried out according to the degree of the descensus and the necessity for the preservation of the uterus. He believed that in minor degrees of prolapsus uteri, with rectocele and cystocele, the Alexander operation, with well-directed plastic surgery of the vagina and perineum, will cure these simple forms. When the prolapsus extends to the introitus, or the cervix points through the vulva, a vaginal hysterectomy, with a well-performed anterior and posterior colporrhaphy and a perineorrhaphy, accomplishes the best results; and the effect is permanent if the vault of the narrowed vagina is sewed firmly to the cut edges of the broad ligament. When it is desirable to save the uterus for the purpose of child-bearing, or to continue the function of menstruation, the cervix must be amputated and an anterior and posterior colporrhaphy and perineorrhaphy must be performed and the uterus firmly ventrofixated to the abdominal wall through a median abdominal incision. Usually all these operations can be performed at one sitting, but if it is desirable to make two operations the posterior colporrhaphy and perineorrhaphy must be done at the same time, say three weeks after the first operations. The author, however, prefers the removal of the uterus, as this operation has been infinitely more successful in his hands. He also deprecated the performance of all operations which close the vagina, as he believed this unnecessary and because he had seen much unhappiness result from this procedure.

For the extreme cases of pelvic hernia, he was particularly pleased with a reprint sent him by Dr. Crile, in which he advocated a very elaborate and extensive operation. For one such case, which occurred in his own practice, he sewed the united vagina and broad ligaments to the abdominal wall, and the result was very satisfactory. However, such extreme measures are seldom called for, as most cases can be cured by the other operations described.

Dr. Hayd then detailed his operation on the posterior vaginal wall and the perineum, in which he cuts out a large triangular piece of the posterior central part of the vagina, and then, with the finger in the rectum as a guide to make tense the obturator fascia and levator ani muscle, he sews these opposing structures in perfect apposition with fine chromic gut, which layer of sutures is buried by bringing together the vaginal mucous membrane by another layer of sutures, and finally the skin is brought together by silkworm gut. This operation lessens the size of the vagina and lengthens it by producing an oblique canal instead of a horizontal one, and by carefully approximating the fascia and levator ani, the *sine qua non* of all perineal operations, the result remains fixed and permanent.

Surgery of the Liver.

Dr. William J. Gillette, Toledo, Ohio, read a paper on this subject, in which, after discussing the control of hemorrhage, the power of the liver to regenerate itself, infection and cholemia, he described a means of controlling liver hemorrhage in certain cases of severe bleeding when the blood vessels can not be easily reached. It sometimes happens that to tie them requires a further enlargement of the lacerated liver substance. This of itself increases the gravity of the patient's condition. Three years ago he was called in haste to see a young girl of 14 years, who had been shot by a target gun, the bullet entering between the eighth and ninth ribs, near the costal cartilage, and passing through the right lobe of the liver, lodging behind the stomach. The low velocity of the bullet had caused it to make a tear rather than a perforation. When first seen the child was nearly pulseless, and had all the evidences of a severe internal hemorrhage. Her face and lips were white and bloodless. The abdomen was opened. An incision was made close and parallel to the costal cartilages on the right side. The abdomen was found full of blood, which could be seen freely oozing from the torn liver. He attempted to control this first with catgut ligatures, but the friability of the tissues prevented. Some time previously he had had an experience with a similar wound of the liver made by a bullet, and had attempted to control the hemorrhage by packing with gauze; but the patient, a strong, robust man, had promptly died from the continued loss of blood. Postmortem revealed that the gauze packing had been entirely inadequate to control it. Having this case in mind, he did not feel like trusting to gauze again, and, inasmuch as it was not controlled by direct ligation, it occurred to him that by passing sutures from within, entirely through the liver substance and through the abdominal wall, making exit between the ribs after the manner of a staple, and tied firmly on the cutaneous surface, that permanent and constant pressure could be made, sufficient to control the hemorrhage without the ligature cutting into the friable liver tissue. Five or six such sutures were now introduced on the proximal side of the wound, each one embracing about three-quarters of an inch of the liver substance. Care was taken to link them together so as to include all the bleeding tissues in their bite. The ligatures emerged between the ribs the same distance apart as they were entered on the liver substance, and when firmly tied all the hemorrhage and oozing ceased at once. Other injuries to the viscera, which were slight, were repaired, a drainage tube inserted, and the abdomen closed. The patient made an uninterrupted recovery. He has since used this suture in two instances, in one of which in removing a very adherent gall bladder he met with a severe hemorrhage which was readily controlled with it. Recovery was prompt. The third case was one in which a hydatid cyst the size of a small cocoanut was removed, together with a large number of gallstones, from a suppurating gall bladder. This patient unfortunately died from peritonitis a few days later, but the hemostasis was perfect.

The author referred at length to the more recent contributions to liver surgery.

Papillary Cyst Adenoma of the Breast.

Dr. Edward J. Ill, Newark, N. J., said that this disease is comparatively rare, but that he has seen eight cases in his practice. There is not very much literature about the disease. Its characteristic symptoms are a clear yellowish-pink to dark bloody discharge from the nipple. On palpating the breast a small tumor can be made out early in the disease which may become multinodular later on. He has observed cases for from a few weeks to eleven, twelve and twenty-one years. The pathologic condition found is a papillary adenomatous mass projecting into the milk duct. It is non-malignant in character. The patient may get well without any interference. When the disease persists, he advises removal of the breast.

DISCUSSION.

Dr. Miles F. Porter, Fort Wayne, Ind., said that cystadenoma of the ovaries and other organs is prone to become malignant, and no one can tell whether the tumor is malignant or not until he has removed it. Some of these tumors are pronounced to be non-malignant by microscopists, but there is recurrence after operation. Others are pronounced malignant, but the disease does not return after operation.

Dr. Joseph Price, Philadelphia, has never regretted the early removal of tumors of the breast for fear they might become malignant. He cited cases in point.

The Byrne Operation in Cancer of the Cervix.

Dr. X. O. Werder, Pittsburg, Pa., described the operative technic employed by Byrne, and said that Byrne places special stress on the importance of thorough and repeated cauterization of the wound surfaces and edges from which cancerous material has been removed, regarding it as the best safeguard against a recurrence of the disease. The most remarkable feature of the Byrne operation, when compared with all other operations undertaken through the vagina for the cure of cancer of the cervix, and one which seems to justify Byrne's conclusions, is the almost uniform absence of local recurrence. While employing the method described by Byrne in his first cases, he invariably followed it by the ablation of the remaining portion of the uterine body and apendages. Subsequently, however, he simplified the procedure very materially by dispensing with the preliminary amputation of the cervix. The principal features of the Byrne operation have been retained, namely, thorough and repeated cauterization of all wound surfaces and edges. The operation differs from the usual vaginal hysterectomy by the use of the cautery knife for detaching the cervix from its vaginal connections, the application of the electrothermic clamps devised by Downes, and the final cauterization of the stump with the dome-shaped cautery. He described the technic as he employs it at the present time. Of the sixteen cases operated on by him, only one died, about four weeks after the operation, from uremia. She is supposed to have suffered from nephritis for ten years previously; the operation, he thinks, may have hastened, but not caused her death.

Indications for Hysterectomy in Puerperal Septicemia.

Dr. Charles Greene Cumston, Boston, stated that hysterectomy applied to the treatment of acute puerperal infection is as yet a mooted question as far as its indications are concerned, and it would be quite as illogical to advise this interference in all serious cases as it would be systematically to condemn it. All surgeons seem to be in accord as to the great difficulty of formulating the indications for this operation, and especially the time when these become formal. To come to a conclusion, all clinical methods of examination and those of the laboratory must be employed. The latter, however, are far from being of equal value, as no positive result can be obtained from a bacteriologic examination of the lochia or blood. Cytologic examination of the blood will give excellent data as far as the prognosis of the type of infection is concerned. Clinically, there is no one valuable sign, but taken together the symptoms obtained by careful intrauterine examination may indicate the necessity of surgical intervention when all other therapeutic procedures have failed. Septicemia occurring at once after labor can not derive benefit from surgery, but, on the other hand, it would appear that hysterectomy is indicated in cases of secondary septicemia with a slow evolution, or those taking on a pyemic type proceeding by successive stages, on the condition that there are no visceral metastases, in which case surgical treatment would be a method of exception.

Abdominal Hysterectomy for Multiple Fibroids Complicated by Pregnancy.

Dr. J. Henry Carstens, Detroit, reported the case of a woman, 42 years old, who was never pregnant before. The tumor was noticed for five or six years, but not accompanied by hemorrhage. Menstruation was regular until May; there was a slight show in June and July. He operated in the middle of August. The growth became rapid during the last three months. Patient recovered from the operation for the removal of the tumors.

These cases are not uncommon; still they are sufficiently rare to warrant reporting them. In nearly all cases the women are sterile; a growth develops, and after some years they become pregnant, which makes one suspect that there was some abnormal condition of the uterus, perhaps some malposition which prevented impregnation, but as the result of the growth the uterus was pulled up or shoved over in one direction or another in such a way that the ova could pass into the uterus and pregnancy occur. This seems to him the correct explanation of the occurrence of pregnancy in sterile women after the development of fibroid tumors.

In reference to general rules for these cases, the cases vary so much that no definite rule can be laid down to govern all cases, but on general principles he thinks cases of fibroids complicated by pregnancy can be left alone if they are subperitoneal and located at the upper half of the uterus. Fibroids located in the lower half of the uterus or in the broad ligament should be removed. Fibroids adherent or complicated with other pelvic diseases should be removed by enucleation, or, in some cases, an abdominal hysterectomy should be performed.

(*To be continued.*)

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Annual Meeting, held in Scranton, Sept. 26-28, 1905.

Election of Officers.

The following officers were elected: President, Dr. William H. Hartzell, Allentown; secretary, Dr. Cyrus Lee Stevens, Athens (re-elected), and treasurer, Dr. George W. Wagoner, Johnstown (re-elected). Bedford Springs was selected as the next meeting place.

Adopted Uniform Plan.

The committee appointed for the purpose a year ago reported in favor of such modifications of their present constitution and by-laws as to make them conform to the uniform plan recommended by the American Medical Association. Pennsylvania was one of the few states that had had the county plan before the matter was taken up by the American Medical Association, but certain details were not in conformity with the uniform plan recommended. The trustees now become the councilors.

Medical Defense and Fraternal Relief.

The society also introduced an amendment to the by-laws providing for medical defense similar to that which has been in force in the Philadelphia County Medical Society, the Chicago Medical Society and a few other local societies for some time.

Action was also taken looking to the provision for the relief of physicians in sickness, as well as for the widows and children of deceased physicians.

(*To be continued.*)

AMERICAN PUBLIC HEALTH ASSOCIATION.

Proceedings of the Thirty-third Annual Meeting, held in Boston, Sept. 25-29, 1905.

The President, Dr. F. F. Wesbrook, Minneapolis, in the Chair.

Addresses of welcome were delivered by Attorney-General Herbert F. Parker, on behalf of the state, and by Dr. Samuel H. Durgin, on behalf of the city of Boston.

President's Address.

The president, Dr. F. F. Wesbrook, Minneapolis, said that in America two causes are operative in rendering it difficult to protect the health of the public, one of which is the lack of real knowledge on the part of the public in regard to the scientific truths which underlie the conservation of its chiefest asset, *namely, its health, and the other is a tendency in* the preservation of individual freedom to lose sight of our obligations to respect the rights and privileges of others who may be less assertive.

The older method of securing experience by experimentation on the public should be superseded by requiring preliminary special training at universities and by boards of health, so that while retaining for the good of the public the service of those already trained and competent, they may be re-enforced and, when necessary, succeeded by those who have received such special training.

Knowledge of the clinical manifestations of disease is important, but often much more than clinical experience and ability is essential. While in scarlet fever, smallpox and certain of the infectious diseases it is nearly always possible to diagnosticate the condition present, and by so doing protect others from infection, there are a number of diseases in which clinical observation alone proves utterly insufficient. As illustrating this he mentioned diphtheria.

The policy of the association should be to anticipate demands for special work and special information along the lines which are closely applicable to public health, and care must be taken that with so many societies the members do not lose interest because they have failed to provide a place and a stimulus for workers in all lines which directly affect the work of the association.

Lessons to Be Learned from the Present Outbreak of Yellow Fever in Louisiana.

Dr. James Carroll, Washington, D. C., read a paper on this subject, which is published in this issue of The Journal, page 1079.

Yellow Fever in Mexico.

Dr. Eduardo Licéaga, Mexico City, said that since the institution of modern methods in the City of Mexico, yellow fever has been diminished to a marvelous extent. He predicts that at no distant date this disease will be completely exterminated, as has been done in Cuba.

Etiology and Prevention of Yellow Fever.

Dr. John Guiteras, Havana, Cuba, confined his remarks to new points that have arisen in the struggle with yellow fever during the year which have been evolved by investigations. The French Commission from the Pasteur Institute, experimenting in Rio Janeiro, produced a case of yellow fever by applying to a non-immune mosquito the eggs laid by an infected mosquito. This raises a very interesting question as to the transmissibility of yellow fever by the progeny of infected mosquitoes. The speaker thinks that by experimentation they have settled this matter in Havana, that an infected mosquito can not transmit infection through its progeny or eggs. He is inclined to believe from a perusal of the experiments of the French Commission that there is some mistake. Marchoux, the French experimenter, acknowledges that he has only one such case. He worked in an infected locality, and it is possible, Dr. Guiteras thinks, that the patient was accidentally bitten by another infected mosquito without Marchoux knowing it.

There is another argument against the transmission of yellow fever by the progeny of infected mosquitoes. It seems to him that it would have been impossible to have eradicated yellow fever in Havana as they have done if that theory is true. In getting rid of yellow fever in Havana, they began to attack the epidemic in the beginning, so that it was comparatively easy to wipe out the disease in that city. This would have been impossible if the progeny of infected mosquitoes had been also infected.

Another interesting point to which Marchoux called attention was that one source of infection is to be found in young children affected with a mild form of yellow fever. Dr. Guiteras said this is not new, as Blair, Chaille and himself pointed this out in their investigations at Key West and in Havana, and they had shown that there were many cases of mild yellow fever among children that were unrecognized who became sources of infection by the mosquito. It was a study of the problem of yellow fever in young children in the yellow fever zone that led him to call attention to and insist on the great danger of mild cases of yellow fever. He has been calling attention to this for many years, not only in cases of young children, but also in young adults, especially of the colored population who are apt to develop mild cases of the disease. These he has always considered the most dangerous transmitters of the infection.

Special attention was directed to the high percentage of hemoglobin found in yellow-fever cases, which he said is an important differential diagnostic point between this disease, typhoid fever, malaria and influenza, three affections that are frequently confounded with yellow fever. In influenza, typhoid fever and malaria the percentage of hemoglobin is low—70, 75, perhaps 80. In malaria and typhoid fever, on the second day of the disease, one notices a decline in the percentage of hemoglobin in the blood. On the other hand, in yellow fever the percentage of hemoglobin is high, very often 100, sometimes above 100, during the first three, four and five days of the disease, and rarely below 90. If the percentage of hemoglobin goes below 90, and the case proves to be one of yellow fever, he considers that there is a complication, or the patient previously suffered from malaria.

Another point that has been of considerable aid to him during the present epidemic of yellow fever, especially in Florida, where they were confronted with the existence of an epidemic of dengue, and where the question came up as to whether or not yellow fever was present, is the diazo-reaction of Ehrlich. The diazo-reaction of Ehrlich is an important diagnostic sign in typhoid fever, but it may be present in other infectious diseases. He could say positively, however, that this is never present in uncomplicated cases of yellow fever, and on two occasions his mind was completely relieved as to the existence of yellow fever during the past summer in the South by finding the Ehrlich diazo-reaction in the urine. He was, therefore, able from his experience in Havana to exclude at once yellow fever in these two cases.

Another diagnostic point is albumin in the urine. Albumin in the urine is a characteristic sign of yellow fever. He insists more than he has ever done before on the importance of this symptom, and on a certain interpretation that must be given to the presence of albumin in the urine. After a careful study of many kinds of fever in Havana, he has found that albumin in the urine is more common in other infectious diseases that he has heretofore thought. It is common in cases of influenza and of typhoid fever, but not so common in malaria. It is only occasionally found in cases of malaria. Albumin in the urine is found in cases of dengue. The special point he brought out was that the quantity of albumin found in the urine in cases of yellow fever is out of all proportion to the other symptoms present.

Dr. Guiteras concluded his remarks by referring to the methods of disinfection that are being employed in New Orleans, and complimented the physicians in charge of yellow-fever cases in Louisiana on the efficient work they are doing.

He spoke of the use of superheated steam for the destruction of mosquitoes, saying that this agent is being used to great advantage in the present epidemic in Louisiana, and it is a valuable and efficient adjunct.

Resolutions on the Yellow Fever Epidemic.

A committee consisting of Drs. John Guiteras, Frederick Montizambert, P. H. Bailhache, James Carroll, William Bailey and Eduardo Liceaga, presented the following resolutions, which were adopted:

Whereas, The results obtained during the present epidemic of yellow fever in New Orleans by the methods of mosquito extermination, and by the prevention of the access of the mosquito to the patients, have been far in advance of the results obtained by the older methods; and

Whereas, It has been possible by the new methods to hold in check and gradually to reduce an epidemic that has taken a firm foothold in the midst of the largest non-immune population that was ever exposed to yellow fever: therefore be it

Resolved, (1) That the association sees in these results a further confirmation of the view that yellow fever is naturally transmitted only by the bite of an infected mosquito. (2) That the association is of opinion that an efficient plan of defense against the propagation of yellow fever at the beginning of an epidemic can be easily established on the basis of this doctrine. (3) That the successful carrying out of such plan depends on a thorough understanding of the mosquito doctrine by the people, and the support that they may give to the prompt and frank reporting and to the proper handling of the first cases and of all suspicious cases. (4) The association wishes further to congratulate the Public Health and Marine-Hospital Service for the brilliant work done by Dr. Joseph H. White and his colleagues in New Orleans, and to urge on all concerned that the said Service be called on to take charge permanently of maritime quarantine along the Gulf Coast.

Election of Officers.

The following officers were elected: President, Prof. F. C. Robinson, Brunswick, Maine; vice-presidents, Drs. J. J. Kinyoun, Glenolden, Pa.; Domingo Orvananos, Mexico City, and Richard H. Lewis, Raleigh, N. C.; secretary, Charles O. Probst, Columbus, Ohio; treasurer, Dr. Frank W. Wright, New Haven, Conn.

Mexico City was chosen as the place for the next annual meeting in 1906.

(*To be continued.*)

AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTO-LARYNGOLOGY.

Tenth Annual Meeting, held at Buffalo, N. Y., Sept. 14-16, 1905.

(*Continued from page 1128.*)

Advantages and Disadvantages of Glasses in Railway Service.

Dr. Nelson Black, Milwaukee, Wis., gave a report of the opinion of ophthalmologists throughout the United States as to the safeness of an employe requiring the use of glasses. The advantages of, and objections to, the protection of the eyes of engine men and firemen by glasses was discussed. The question of allowing engine men, who have been a long time in the service, to wear glasses for constant use, when their vision has fallen below the required standard, but can be brought up to standard by lenses, has been receiving very serious consideration by railway officials. Many railroad companies allow their old engine men to run with glasses, requiring them to carry an extra pair. An opinion was asked as to the safety of such an engine man, and the following was given: "It is my opinion that a railroad employe (engine man or fireman), who has been in the continued service for a period of not less than five years, and who on re-examination falls below the required standard of vision, and such vision can be brought up to said required standard with glasses, his color perception meeting the required standard, and there being no ocular disease, is a safe employe. Such employe should be required to carry at least one extra pair of glasses. He should also be re-examined semi-annually to ascertain if there has been a further decrease in vision, and if the glasses fully correct the visual defect."

Fixation of External Rectus Muscle in Nystagmus and Paralysis.

Dr. J. Elliott Colburn, Chicago, reported a case of nystagmus, one of paralysis of the right internus, and another of motor paralysis of the third nerve.

Ocular Origin of Migraine.

Dr. George M. Gould, Philadelphia, read an article on this subject which will be published in The Journal.

Retinal Changes as an Aid to Diagnosis in Vascular Degenerations.

Dr. Thomas A. Woodruff, Chicago, called attention to the slight anomalies that are recognized from time to time which show themselves in alterations in the caliber and contour of the retinal vessels. In some cases these changes may be so slight as to be overlooked. A very careful and closer study of the fundus will enable one to detect slight structural changes in the retinal vessels, which will lead him to form the conclusion that there is commencing degeneration of the arterial walls, also in the smaller arteries elsewhere in the body, signifying an arterio-capillary fibrosis. Tortuosity of the vessels is not a positive sign, unless it is confirmed by other variations from the normal which are found in the early stages of arterial degeneration. These changes are readily recognized by an ophthalmoscopic examination in the early stages of arterial degeneration, and if appropriate treatment is promptly instituted the disease can be arrested and a favorable prognosis given.

Formalin in the Treatment of Diseases of the Ear, Nose and Throat.

Dr. Otto J. Stein, Chicago, narrated his personal experience with this drug in a variety of diseases of the ear, nose and throat.

The Treatment of Recent Embolism of the Retinal Arteries By Digital Massage.

Dr. H. V. Würdemann, Milwaukee, Wis., gave abstracts of all the cases he could find in the literature, including four of his own, describing the treatment in detail. Two of his cases were completely cured, and two were benefited by the massage, as well as a number of the cases reported in the literature. This treatment was strongly recommended by the author, as yielding better results than any other form of treatment. In fact, older methods, unassisted by massage, are deemed of little use.

Dextrophoria.

Dr. Frances Vale, New York, said that this condition is found in the examination of the field of vision with the tropometer. It shows a tendency for the visual lines to turn to the right or left under the influence of the direct innervation of the muscles. It has probably an anatomic cause. It is found associated with esophoria and exophoria, and in the operative correction of all cases of lateral imbalance is a useful indication of a necessary procedure.

Advancement Operation versus Tenotomy.

Dr. Edw. J. Bernstein, New York, assumed that the position of Landolt is correct, that tenotomy of the recti is unjustifiable except under rare conditions, as it substitutes two weak muscles for one normal muscle and one relatively weak one, thereby producing insufficiency in amplitude in both lateral directions. The technic of the operation is the Weeks advancement. With this operation the author corrects not only actual strabismus, but also muscular insufficiencies which are not amenable to non-surgical means.

Clinical Measurement of Torsion.

Dr. Lucien Howe, Buffalo, pointed out the difference between torsion with convergence and torsion with parallel axes. He has devised three instruments for measuring torsion with convergence, which were exhibited and demonstrated.

Intranasal Pressure a Cause of Diplopia and Headache.

Dr. Kate Wiley Baldwin, Philadelphia, stated that pressure from the left middle turbinal acts as an irritant and causes diplopia. There is no relief from treatment directed to the eyes but disappears entirely soon after a middle turbinectomy. In a case occurring after a very serious nervous strain recurrence took place several months later. The patient was relieved by division of a postoperative synechia. When headache is caused by intranasal pressure the nasal tissues usually are found hypersensitive, especially those on which pressure causes pain in some particular part of the head or in the eyes. When pain is unilateral only one side of the nose is abnormally sensitive. This sensitiveness disappears after operation.

Treatment of the Diseased Attic.

Dr. F. C. Hotz, Chicago, stated that success in the treatment of chronic aural discharges depends chiefly on the personal attention of the attending physician, particularly if the attic is involved, ere the routine treatment of syringing, use of the gouge, drains and instillations of various solutions is absolutely ineffective. The diseased conditions should be attacked directly by instruments with which the attic can be cleaned thoroughly and apply the proper solutions directly to the diseased wall. Instruments were shown and the treatment described.

Some Displeasing Results of the Mastoid Operation.

Dr. J. A. Stucky, Lexington, Ky., said that it is very essential that general practitioners should know more of suppurative mastoiditis, how to recognize it, and what treatment to urge. Important lessons learned from failures and unpleasant after-effects of the operation were pointed out. Some of the most displeasing after-effects are protracted discharge, obstinate granulations, atresia of the external auditory canal, slow healing of the wound, unsightly scar, and post-auricular fistula. The most important of these are due to: 1. Neglect in urging the operation early, instead of waiting until the disease has completely invaded and infected the contiguous structures of the antrum, and the resistive and recuperative power of the patient is undermined by the absorption of the retained septic material. It is just as dangerous to wait for external evidence of pus formation in the mastoid process as it is in the abdomen in appendicitis. 2. Want of proper preparation of the patient before operating. The presence of indican in the urine is a most important factor in toxemia, high temperature, and slow and unsatisfactory recovery which follows a thorough operation. 3. Want of thoroughness in removing all diseased and infected tissue, and giving unobstructed drainage to every part of the wound. 4. Carelessness and indifference shown in after-dressings of the wound, and in diet and quietude of the patient for several days after the operation.

The Submucous Resection of the Septum.

Dr. William Lincoln Ballenger, Chicago, described the various methods for the submucous resection, and presented a critique of the methods. He described his own method with the swivel knife for removing the cartilaginous septum through an anterior incision and exhibited his swivel knife, together with specimens removed with it.

The Front Bent Gouge in Mastoid Operations.

Dr. W. S. Bryant, New York said that this gouge aids the operator in saving time, gives him security, and enables him to carve the bone with perfect precision. It does away with accidental injury to the sigmoid sinus, even when irregularly placed. It permits the surgeon to remove the posterior canal wall without injury to the facial nerve. With its aid the operator can remove the outer wall of the attic and hanging wall of the meatus without accidentally opening the middle fossa. He can smooth out the bony excavation without danger of going further than he intends. When the mastoid process is sclerosed this gouge enables the operator to proceed rapidly with the excavation of the bone, without increased risk. It is not necessary to use a mallet with this gouge, thus sparing the patient the infliction of disturbing blows on the head.

The Oto-Projectoscope.

Dr. M. A. Goldstein, St. Louis, Mo., gave a practical demonstration of this apparatus, which consists of a combination of the modified and simplified epidiascope and the Brunton otoscope. It may be used in the class-room without the otoscope attachment for projecting anatomic and pathologic specimens in their natural color, depth and details. Photographs, diagrams and all forms of illustrations may be projected directly on the screen without further preparation.

Relations Between Medical Practitioners and Eye Specialists.

Dr. James A. Spalding, Portland, Me., said that many medical men will sign petitions to legalize opticians as scientific fitters of lenses, send patients with diseased eyes and foreign bodies in them to opticians, consult opticians for diseases of their own eyes and the fitting of lenses, and send friends and patients to opticians even when in their own town there reside educated medical men who have specialized in diseases of the eyes. The reasons for this are thoughtlessness, jealousy, belittlement of the skill demanded in fitting glasses, desire to have the optician and family of the patients, irritation at the large fees demanded by oculists, and the belief that the specialty is overrated, and that many of the practitioners are undereducated.

Specialists must deserve recommendations from practitioners. They must be well educated and ethical men. No one can be a good specialist in six weeks. If well-educated specialists should fail in proper medical support, they can not gain a living in competition with hospitals, which take the operations, and opticians who advertise for and get the refractive cases in a vast majority of towns and cities in the land. Just as physicians organize, so specialists should organize, and as an organization publish under the auspices of their publication committee papers on diseases of the eye. They should teach that eyes with imperfect sight are diseased eyes, and need proper treatment at the hands of medical specialists in the way of proper lenses. They should issue their own set of test types and hang them in every school. They should send a representative into every normal school to test the eyesight of the pupil teachers and lecture before these future teachers about the eye. They should keep in touch with the colleges and their students, some member following each class through its four years of college life. They should furnish to medical practitioners a fee table, for people of moderate means who wish to know the cost beforehand. They should refuse to buy lenses of opticians who make it a rule to fit lenses. Or, better still, they should furnish their own lenses just as hosts of medical practitioners prescribe their own medicine, and so retain their patients and their means of living.

Dr. L. A. W. Alleman, Brooklyn, N. Y., said that ophthalmology should be taught as a necessary part of a medical education and not as a specialty. Personally, he does not attempt to cover the entire field of ophthalmology. He does not advise the student to learn to use the ophthalmoscope, and he feels reasonably successful, if, at graduation, his student has learned to recognize the cases which he may safely and properly treat, and those which are of so serious a nature as to at once require the assistance of the specialist. The points which the author strives to impress on the student are the assistance that he may expect from an examination of the eye in forming a general diagnosis; also the necessity of recognizing ocular disorders as a factor in the causation of general disease—the systemic causation of many diseases of the eye.

The Mechanism of Accommodation and Astigmatic Accommodation.

Dr. Edward Jackson, Denver, Colo., said that recent physiological examinations have shown that the increased refraction of crystalline lens during the accommodation accompanies relaxation of its suspensory ligament, but that the lens does not at this time become more spherical. Skiascopy also shows that increased lenticonus attends accommodation, and that each lens presents its individual peculiarities of aberration and astigma. When freed from the tension of its capsule, it tends to assume a shape determined by the development of the lens fibers, and on these may depend astigmic accommodation.

The following papers were read: "Electric Ophthalmia," Dr. Edward N. Meckel, Pittsburg; "Fallacies in Ophthalmology," Dr. Joseph E. Willetts, Pittsburg; "Radium," Dr. W. Freudenthal, New York; "Physical Examination of the Mastoid," Dr. A. H. Andrews, Chicago; "Hemorrhage in Nose and Throat Operations," Dr. Emil Mayer, New York; "Angio-Endothelioma of the Middle Ear," Dr. Joseph Beck, Chicago; "Acute Eustachian Salpingitis," Dr. Frank H. Koyle, New York; "Middle Turbinate Body in Diseases of the Accessory Sinuses," Dr. Charles M. Robertson, Chicago; "Interstitial Keratitis," Dr. Thomas Faith, Chicago; "The Diseased Faucial Tonsil," Dr. William R. Murray, Minneapolis; "Clinical Significance of Otalgia," Dr. Percy Fridenberg, New York; "Dendritis Keratitis," Dr. George F. Keiper, Lafayette, Ind.

Therapeutics

[It is the aim of this department to aid the general practitioner by giving practical prescriptions and, in brief, methods of treatment for the diseases seen especially in every-day practice. Proper inquiries concerning general formulae and outlines of treatment are answered in these columns.]

Herpes Zoster.

Leale, in the *New York Med. Jour.*, discusses this condition from a pathologic standpoint and states that he believes the disease to be a nervous affection due to an acute hemorrhagic inflammation of the posterior ganglia and trunks of the nerves supplying that portion of the skin on which the characteristic eruption is situated. In the treatment, therefore, we must bear in mind we have to do with an acute inflammatory condition involving certain structures of the nervous system and perhaps associated with a mild form of cerebrospinal toxemia.

As soon as the disease is recognized the patient is put to bed and given a laxative, a fever prescription may be given, and a light diet, preferably milk. The author then directs treatment to the causative seat of the disease. Counterirritation is applied over the roots and trunks of the nerves involved. By this means the congestion is lessened and the absorption of the inflammatory products is hastened by going directly to the seat of the trouble and thereby favorably affecting the symptoms. The author recommends the use of dry cups, which should be applied over the ganglia of the posterior roots and over the points of emergence of the nerves involved. In order to do this properly it is necessary to have at least a general idea of the location and relation of the spinal nerves. The ganglion is developed on the posterior root of each of the spinal nerves, and they are situated in the intervertebral foramina external to the point at which the nerves perforate the dura mater. Having located the posterior roots involved, the cups are applied just to the affected side of the spinous processes and allowed to remain long enough to insure their maximum suction power. After the first set is removed they may be reapplied if deemed necessary. A few cups are then applied to the location of the emergence and over the course of the nerves involved. In this the physician is guided by the seat of the pain, hyperesthesia, and by the location of the eruption. If the cups are carefully and accurately applied the author claims a shortening of the duration of the disease and a very great amelioration in the severity of all the symptoms, especially the pain. Cups should be applied in the disease and sometimes even before the eruption has appeared. The cupping is repeated every twenty-four hours, preferably at bed time. In this way a nocturnal paroxysm of pain can often be prevented.

It is essential to protect the vesicles and to prevent their rupturing. This is best accomplished by the application of collodion. If the vesicles rupture a dusting powder is most satisfactory:

℞. Zinci oxidi
Pulv. amyli, āā........................℥i 30|
Acidi borici ....ʒiiss 10|

M. Sig.: Apply locally to the vesicles and cover with sterile cotton dressing.

After an attack is over general tonics, a liberal diet and careful hygienic measures are usually indicated.

Cerebrospinal Meningitis.

Hogner, in *American Medicine*, reports cases of this disease successfully treated by the intramuscular injection of mercuric chlorid. In the author's opinion the intravenous route is the best for injections. If the fluid is injected extravenously it causes considerable smarting, and hard, very annoying infiltrations, swellings, stiffness, etc.; sometimes even gangrene may result. The technic for the intravenous injection is simple: "Take a 2 c.c. morphin syringe and inject into a large vein, which is readily accessible (with or without previous constriction of the upper part of the limb). As a rule I use a vein of the forearm or lower part of the upper arm, but sometimes I use a vein of the legs or one of the scrotum. The injection should always be given very slowly and if, when it is started, swelling or pains occur (I do not mean the insertion pain), then the point of the needle is placed extravenously, and must be corrected, or the needle should be withdrawn and inserted in another place. If the smallest quantity of the fluid has been injected extravenously the patient should be given at once a hard, thorough massage, however painful it may be, for thus only can the consequences be prevented.

"For intravenous injections I use the finest, shortest and best steel needles; for intramuscular injections I have very coarse needles one and one-half inches in length. In the cases reported I injected a plain distilled water solution, but it is better to add some sodium chlorid. For ten years in the treatment of syphilis I have used:

	Parts.
Mercuric chlorid	1 to 2
Sodium chlorid	1 to 9
Distilled water	1,000

"One can safely inject from 1 c.c. to 4 c.c. of this solution, i. e., from 2 mg. to 8 mg. of the mercuric chlorid. Intravenously 8 mg. is the maximum dose. Generally I inject from 2 mg. to 4 mg., and have in more than 5,000 injections never seen any bad symptoms result from the injection."

Alopecia.

Walsh, in the *Journal of Medicine and Science*, has used the following with gratifying success in preventing this condition:

℞.	Acidi salicylici	ʒiii	12
	Acidi carbolic	ʒi	4
	Olei ricini	ʒii	8
	Alcohol q. s. ad	℥vi	90

M. Sig.: Apply freely to scalp once or twice daily.

Fissure of Anus.

In the treatment of this condition, Katzenstein, in *Bull. Gen. de Therap.*, recommends the following ointment:

℞.	Cocainæ hydrochlor.		
	Ext. belladonnæ, āā	gr. i	06
	Ichthyol	ʒiss	6

M. Ft. ungt. Sig.: Apply twice daily.

Ergot in Labor.

Applegate, in *American Medicine*, discusses the therapeutic value of ergot during labor. He states that the drug has no place in the first stage of labor. In normal labor, as is well known, the rhythmic contractions of the uterus are accompanied by gradual thinning and relaxation of the cervix, while under the influence of ergot the predisposition is to constriction and rigidity, particularly of this portion of the uterus, and the fact that it is valuable, or even safe, in uterine inertia can not be substantiated. If rest for a time, friction over the fundus, and stimulation with strychnin or quinin, fail to establish the normal first stage, it is far better and safer to complete the dilation manually and to deliver instrumentally, than to prescribe ergot prematurely, with its attending dangers. The dangers from the administration of ergot are threefold: 1, Rupture of the uterus; 2, asphyxiation of the child or paralysis of the fetal heart from compression; 3, retention of the placenta and membranes. Complete rupture of the body of the uterus, in this author's judgment, rarely occurs from the premature administration of ergot, extensive lacerations are not so rare. Until it is definitely ascertained that descent or partial protrusion of the placenta through the cervical canal has taken place, the administration of the ergot should be regarded as premature, notwithstanding the opposite opinion held by some well-known authorities.

A dram of the fluid extract administered immediately after the termination of a long, tedious labor, or when uterine inertia has been a factor, is unquestionably of value as a preventive measure, since slow involution inevitably follows such a labor, but for the control of established hemorrhage the effects are indicated at once, and far better results can be obtained by the administration of aseptic ergot hypodermically.

A distinction, however, should be made between private and hospital practice; in the latter, with competent resident physicians to compress the uterus in the proper way and manner, to pack in an emergency, or to administer ergot hypodermically, together with trained nurses to administer a hot vaginal douche (temperature from 110 F. to 115 F.), ergot is rarely needed as a preventive measure. Ergot is also of undoubted value following placenta prævia, for the purpose of closing the sinuses of the abnormal placental site, both for preventing too free bleeding and septic infection.

To obtain, then, the greatest therapeutic value of ergot in labor, its administration should be limited to, or near, the end of the third stage, administered by the mouth when indicated for the prevention of hemorrhage, and hypodermically when indicated for the control of hemorrhage.

Medicolegal

Privilege in Federal Courts—Health Stipulations.

The United States Circuit Court of Appeals, Third Circuit, says that at the trial, in the United States Circuit Court for the District of New Jersey, in the case of Doll vs. Equitable Life Assurance Society, objection was made to allowing a practicing physician and surgeon of New York, who had attended the sister of the insured in her last illness, to testify as to the cause of her death. The ground of this objection was that a statute of the state of New York prohibited a physician or surgeon from disclosing "any information which he might have acquired in attending any patient in a professional character and which information was necessary to enable him to prescribe for such patient as a physician, or do any act for him as surgeon." Counsel contended that, inasmuch as the contract of insurance was made in the state of New York, the law and usages of the place of the contract should govern in matters of construction affecting the validity of the contract and the rights of the parties, and that, therefore, this statute was controlling in the trial of this case. But the Circuit Court of Appeals thinks that the judge of the Circuit Court committed no error in admitting the testimony objected to. It says that the contention stated confused those laws which enter into and form a part of the contract, or with reference to which the contract was made, with those, merely, which govern remedy and procedure. The prohibition of the New York statute is a rule as to evidence or procedure, and does not enter into the contract of insurance. The interpretation of the contract does not at all depend on it. The rule affects the remedy and not the contract. In such cases the law of the forum (of the place where legal redress is sought) and not of the place of the contract, must govern. The New York statute, therefore, was not applicable to the trial in the United States Circuit Court for the District of New Jersey. Section 721 of the United States Revised Statutes, providing for the application of state laws to trials in the United States courts, had no relevancy to the point here under consideration. The Supreme Court of the United States, in Connecticut Mutual Life Ins. Co. vs. Union Trust Company, 112 U. S. 250, merely decided that the provision of the New York statute here referred to was obligatory on the court of the United States sitting *within that state.* Another thing said by the United States Circuit Court of Appeals in this case is that courts have been reasonable, and sought to protect the beneficiaries of life insurance policies from careless or ill-considered statements as to prior health, by not holding non-serious ailments or those not material to the risk, within the warranty of a statement by the insured, but it will not do, by too great refinement of argumentation, to fritter away the protection which these stipulations as to previous illness are properly intended to give to the insurer. They must receive a sensible and reasonable construction.

Physicians as Expert Witnesses and Their Opinions.

The Supreme Court of Alabama says, in Braham vs. State, a homicide case, that a physician, as an expert, having testified in answer to a hypothetical question that under the hypothesis stated he would say the person was of unsound mind, it was proper on cross-examination for the state to test the accuracy of his information as to the causes of insanity. The jury is not concluded by the opinions given by experts on the question of whether sanity exists or not, and, while the court pronounces on the competency of witnesses as experts, it is the province of the jury to measure the weight of their opinions. In order that the jury may have a proper appreciation of the value of such opinions, it is entirely competent to develop on cross-examination the extent and accuracy of the expert's knowledge of the particular subject on which he has been called to testify as an expert. Another witness in this case testified on the direct examination that he was a practicing physician, and had been such since 1897; that he was assistant county physician and had seen the defendant a number of times in the county jail; that he treated the defendant for a severe cold, which turned out to be measles; and that he treated him again a few days before the trial. He further testified that he saw the defendant often in the jail, and talked with him, he supposed, a dozen times; that his conversations were chiefly about his physical condition; that from his acquaintance with, observation of, the defendant, and from his professional knowledge, he would say that the defendant was sane. On cross-examination the defendant asked the physician this question: "Are you an expert on insanity?" The court has been unable to find any case in which the precise question presented has been considered. It is undoubtedly the law that the court must determine the question of the competency of a witness to testify as an expert, and that all evidence which goes to the competency of such witness should be addressed to the court. It is also true that, after a witness has been held competent by the court, it is the province of the jury to determine the weight of the evidence of such witness, and, as ruled above, a jury is not concluded by the opinion of experts, but must weigh such opinions with the other evidence; and in order to afford the jury ample opportunity to test the value of such opinions it is competent on cross-examination to inquire of the expert as to the extent and accuracy of his knowledge with reference to the particular subject on which, as an expert, he has expressed an opinion. As was said in De Phue's case, 44 Ala. 39, "A physician is an expert, and as such he may be asked questions which develop his capacity to form a correct judgment on the experiences of his profession." In this respect it might be competent to ask the physician if he had a diploma, or from what college he graduated, or the extent of his experience in the treatment of persons afflicted with insanity. In this way some of the data would be furnished on which the court, in the first instance, would be able to draw its conclusion as to the competency of the witness, and the jury, in connection with the evidence on which the opinion is based, could measure the weight to be accorded the opinion expressed. But this court submits that the question under consideration did not call for any data of the kind above referred to, nor data of any kind, but simply called for the opinion or conclusion of the witness as to his capability; and to have allowed an answer to it would have been to substitute the witness for the court and jury, whose duty it was to pass on the competency of the witness and the weight of his evidence. It was insisted by counsel that the question should have been allowed because it called for a fact peculiarly within the knowledge of the witness. But not every fact that lies peculiarly within the knowledge of a witness is competent evidence. The court notes, too, the fact that the witness, by his evidence, made himself competent to express an opinion that the defendant was of sound mind, aside from the fact that he was an expert.

6 Pathology of General Paralysis of the Insane. J. D. O'Brien, Massillon, Ohio.

1. Digitalis in Valvular Heart Disease.—Goepp says that digitalis increases the contractions of the heart and lengthens the intervals of rest (diastole), and that at the same time the nutrition of the muscle is increased because more blood is forced into the coronary arteries. The indication for digitalis is found in the dynamic state of the circulation, the precise nature of the cardiac lesion being of minor importance. It may be indicated in any form of valvular disease and it is not contraindicated even in aortic insufficiency. Contraindications for the use of digitalis are: hypertrophy with established compensation, and degeneration of the myocardium, and high arterial tension. The cumulative action of digitalis may be disregarded and the administration kept up continuously for a considerable period. The best preparation, he states, is the infusion made from the powdered leaves of digitalis, and not, as is sometimes the case, by diluting the fluid extract. Digitalin is a useful preparation and can be given hypodermically. It should be given in considerably larger doses, he thinks, than is usually recommended. It is well to begin with 3 mgm. (1/20 grain), but no hesitation need be felt in increasing the dose up to 5 mgm. or 8 mgm. (1/12 or ⅛ gr.)

2. Diverticulums of the Esophagus.—Morgan describes and classifies esophageal diverticulums, details symptoms, etc. In diagnosis he advises the use of two tubes, which may be passed simultaneously; after one tube is passed into the diverticulum, a second tube is passed along side and so guided into the stomach or into a second diverticulum. By the introduction of two tubes into different cavities these may be explored separately. In accessible esophageal diverticulums in the cervical region, surgical procedures for radical cure are available, such as obliterating the cavity by invagination or the establishment of a fistula from the borders of the diverticulum to the skin, to afford drainage for the sac, etc. In nonsurgical cases, the conditions may be palliated by keeping the diverticulum empty, and cleansed by irrigation. Astringent or antiseptic applications or irrigations may also be employed to relieve inflammation and ulcerative conditions in the sac. As the greatest trouble in these cases arises from starvation, so the greatest results of treatment, often amounting to symptomatic cure, may be obtained from proper nutrition. When dysphagia is only moderate a sufficient amount of food can sometimes be introduced into the stomach by natural deglutition, by careful selection of easily swallowed foods, careful eating, and by keeping the esophageal passage open and straight by the sound or bougie. When the power of swallowing is greatly impaired or entirely abolished, gastrostomy and feeding through the fistula affords one method of keeping up nutrition. When dysphagia is extreme and the esophagus passable by the stomach-tube, a far better method of feeding is by gavage, which the patient can learn to perform for himself. An entirely adequate amount of food can thus be introduced into the stomach without excessive discomfort, through the natural passages instead of a troublesome artificial fistula, and without the necessity of a formidable operation. The following are some of the foods which Morgan says may be included in the dietary: Beef juice, rich soups and broths, including those containing cream, eggs and wine; puree of all vegetables which do not have tough fiber, among them being puree of spinach, beans, peas, celery, asparagus and potatoes; milk and cream; cocoa, chocolate, coffee, tea and some wines; eggs, raw or soft; scraped meat and fish chowder; porridge made from thoroughly cooked breakfast cereals; a few sweets, such as bees' honey, calf's foot jelly, and simple custards. Once a week the patient is instructed to masticate thoroughly several mouthfuls of some hard substance like crackers with butter, or bread with butter, before one or other of the meals, and even to swallow some portion of it in order to keep up the secretion of saliva in the mouth. By immediately washing out the diverticulum and esophagus no harm is done.

3. Therapeutics of Acute Insanity.—Brower says that insanity is a profound error in general metabolism, which may sometimes be overcome by alteratives; mercury, potassium iodid, and the chlorid of gold and sodium. In considering the therapeutics of acute insanity, the physician must bear in mind the necessity of attention to the general constitutional state of the patient. Rheumatism, gout, tuberculosis and syphilis require special consideration. Special attention must also be given to elimination by the bowels and kidneys. In-

testinal fermentation, when present, must be diminished by intestinal antiseptics, of which Brower believes that salol and zinc sulphocarbolate are among the best. Disorder of the gastrointestinal tract is one of the most common errors in these cases. Colonic impaction is common, and is frequently overlooked. He states that relief of this condition by aloetics and flushing, when this is resorted to early, will often change the whole aspect of the case. Brower insists on the importance of a generous diet for these patients, and states that if the mental condition of the patient interferes with this forced feeding should be resorted to. In case this is necessary, the nasal tube should be used, unless there is some condition in the nose which would interfere with its use; in that case, the esophageal tube will have to be used. He calls attention to the necessity of controlling the insomnia and advises caution in the use of chloral and of hyoscin hydrobromate.

5. **Cancer of the Corpus Uteri.**—Hammond reports three cases of cancer of the body of the uterus illustrative of interesting points in the diagnosis of this disease. He states that it is a fact of peculiar interest that malignant disease of the cervix occurs frequently in comparatively young women. During the past year, he says, two women, each aged 34, with inoperable carcinoma of the cervix, applied at the Samaritan Hospital for treatment. He lays especial emphasis on the importance of early diagnosis in these cases and states that every woman who is bleeding should be subjected to a careful pelvic examination. He cautions the physician against waiting for the "classical" symptoms of pain, hemorrhage, fetid discharge and cachexia. The appearance of hemorrhage one or two years after the menopause, he says, is strong presumptive evidence of cancer. In some cases, he states, instead of hemorrhage, a slight watery discharge, with a characteristic unpleasant odor, is an early symptom of the disease.

11 *Case of Acute Internal Hydrocephalus. T. Diller, Pittsburg, Pa.
12 *Case of Abdominal Pregnancy Undiagnosed Until After Operation. A. J. Ronginsky, New York.

7. **The Individual Treatment of Diabetes Mellitus.**—Stark advises the treatment of the individual patient in diabetes mellitus, rather than the arbitrary treatment of the disease by stereotyped methods. The severity of the pathologic process can not be measured by the amount of sugar in the urine. The physician should study the power of the patient to assimilate carbohydrates; his general state, whether anemic, plethoric, obese, or emaciated; his mental attitude, his digestion, his ability to maintain nitrogenous equilibrium, the complications, and the preferences of the patient as to diet. Patients can not be put on a diet that starves them of carbohydrates, but the amount taken can be lessened. Under prophylactic treatment the author advocates a modified diet for the children of diabetics, with a systematic examination of the urine. The occurrence of an excess of uric acid may be a forerunner of diabetes. The patient should be restrained from gratifying his appetites for food and drink. If emaciated and weak, a diet of increased fats is valuable. For glycosuria and polyuria, the author states that codeia should be given only in very moderate doses. For the skin lesions about the genitals he uses a soothing lotion and protective application. In bad cases catheterization for a time works well. When diabetic coma is established very little can be done. To prevent coma, he uses alkali-therapy, purgation by croton oil, and blood letting if necessary.

11. **Acute Internal Hydrocephalus.**—Theodore Diller reports this case, which was that of a girl who died at the age of 4½ years of what, at the autopsy, was found to be internal hydrocephalus. The cortex was nearly smooth, the convolutions and fissures being almost entirely obliterated. The brain resembled a bladder, and from the distended ventricles about a pint of clear fluid escaped. The condition apparently began with an obscure febrile attack at the age of 2½ years. Six months later, a double convergent squint developed, and after that the manifestations of the internal pressure steadily progressed until the patient became totally helpless and died of exhaustion.

12. **Abdominal Pregnancy Undiagnosed Until After Operation.**—Ronginsky's patient was seen at various times by fourteen physicians, yet it was not until an exploratory laparotomy was performed that it was discovered that the underlying condition was an ectopic pregnancy. The age of the fetus was about 3½ months, and the placenta was attached to the small intestine, and to the ovarian end of the tube. The symptoms had at first simulated indigestion and spasm of the intestine, and later a condition of chronic intestinal obstruction developed. The patient grew progressively more anemic and emaciated, and went into shock after the operation, dying three and a half hours later.

13 *Methods in Medicine. L. F. Barker, Chicago.
14 *Medical Treatment of Gastric Ulcer and Hyperchlorhydria. F. C. Shattuck, Boston.

13. **Methods in Medicine.**—Barker calls attention to the various advances in recent years in the science of medicine. He states that the aspects of scientific medicine, the theoretical and the practical, ought to work together and that medical science and medical art should live in a state of wedlock. Scientific medicine does not undervalue observation or good clinical work; it does not maintain that the laboratories are the only places whence illumination comes. On the contrary, scientific medicine realizes to-day more than ever before that the ideas which stimulate experimental work which will be fruitful for diagnosis and treatment must be gained, in part at least, from the sick people themselves. A scientific physician, Barker states, should have a large bedside experience and should be familiar, from personal observation on human beings, with the forms of disease on which he is working. He should be able to make accurate diagnoses and thorough prognoses, and should have a knowledge of the various remedies which empiricism has recommended. He says that it has taken thousands of years to elaborate the present methods of clinical examination, and the results which have been achieved give us increased confidence in man's power in medicine. If the past is an index of the future, Barker thinks that we need not hesitate to assert with regard to medicine that, in time, through the further applications of scientific methods, "we shall know; we shall be able to predict; we shall gain the power to control."

21. **The Menopause.**—Upshur reviews the symptoms most commonly occurring in women at this period of life and says that the treatment should aim at sustaining the system in such a way as to alleviate nervous irritability and to supply stimulus and nourishment which will keep the patient as nearly as possible at the normal standard of health. He states that drugs are not to be administered in any case in which simpler and less active agents will accomplish the same end, and emphatically protests against the injudicious prescription of narcotics or alcoholic stimulants because of the great danger of making the patient dependent on them. Hygienic regulation of all the functions and habits should be attended to, and especially the patient should keep early hours.

25. **Use and Abuse of Fresh Air and Overfeeding in Tuberculosis.**—Prioleau calls attention to the fact that while fresh air in abundance is to be desired above all else in the treatment of tuberculosis, it is better for the patient to be comfortable indoors than to be uncomfortable in the open air. Nothing, he states, is more unpleasant to an invalid than being cold, and there are a few things more harmful. Besides the discomfort of it, cold stops digestion, chills the periphery of the body and congests the internal organs. He states that the proper feeding of the patient is as important as fresh air. A tuberculous patient is often required to dispose of a full *tuberculosis diet*, without regard to his digestive or assimilative powers. Ordinarily the digestive powers of a consumptive are poor, and forced feeding overburdens the stomach and destroys any natural appetite a patient may have. A consumptive should never know hunger, but he should be allowed the privilege of an appetite. As the appetite is generally poor in these cases, a tuberculous patient should be required to eat more at the three principal meals than he feels like doing, as it is a well-known fact that a tuberculous patient can digest and assimilate more than he feels like eating. Prioleau concludes his article by stating that each patient should be supplied with fresh air and nutritious food, according to the comfort of his body and the power of his digestion, remembering always that the personal equation enters into each case.

37 The Growth of Pneumococci and Streptococci in Blood Serum. W. T. Longcope, Philadelphia.

29. **Study of Pneumococci.**—The investigations carried on by Park, Williams and others were planned after consultation with the members of the commission for the investigation of acute respiratory diseases of the health department of the city of New York, but were otherwise entirely independent of that body. Two hundred patients were examined for the presence of pneumococcus, with the following results: Typical pneumococci were present during the winter months in the throat secretions of a large percentage of healthy individuals in the city and in the country. A higher percentage of atypical strains of pneumococci has been obtained from healthy persons than from those suffering with pneumonia. In the latter cases the atypical strains may have been overlooked, because of the larger number of typical pneumococci present. Many of the atypical strains seemed to be closely related to the streptococci. The so-called *Streptococcus mucosus* of Schottmueller, which has hitherto been classed with the distinct streptococci, is placed as a definite variety among the pneumococci, and it is recommended that the name be changed to *Streptococcus lanceolatus, var. mucosus.* A lower percentage of strains of pneumococci virulent for rabbits in the doses used was obtained from normal individuals by rabbit inoculations of mass cultures than from cases of pneumonia by the same method. Since the virulence of pneumococci may be rapidly increased for a susceptible species of experimental animal by successive passage, and since pneumococci obtained from most pneumonias are more virulent for experimental animals than are those obtained from healthy individuals, therefore, the virulence of pneumococci from cases of human infection is probably increased for human beings. Hence, cases of pneumonia, to a certain degree, should be considered as contagious, and, since the virulence of the pneumococcus may be quickly increased and since the organism is very prevalent in normal sputum, all possible measures should be taken to restrict public expectoration. By repeated inoculations into sheep of a pneumococcus strain, a specific protective power of this serum for mice is developed against the homologous strain and against certain other strains, one morphologic variety (*Streptococcus lanceolatus, var. mucosus*) being thus clearly differentiated from other strains. Coincident with this production of protective power, a slight specific increase of the sheep serum in phagocytic power *in vitro* was observed with some strains of pneumococci, all strains of *Streptococcus lanceolatus, var. mucosus* acting similarly with the serum produced by the inoculation of one strain; the strains of some varieties, however, have shown no definite relationship between the phagocytic power and the protective power of the serum.

30. **Agglutination Pneumococcus.**—The report made by Collins is a part of the work on pneumonia planned by the pneumonia commission. Owing to unavoidable circumstances, the work done was curtailed considerably; hence, Collins is able to make only the following preliminary report: 1. Pneumococci, by reason of their agglutinating properties exhibit a tendency to separate into numerous groups similar to streptococci. 2. *Pneumococcus mucosus* forms a distinct and consistent variety. The production by it of common agglutinins for some pneumococci and the resistance of the agglutinins produced by it to absorption by the streptococcus indicate a nearer relation to the former than to the latter organism. 3. The agglutinating substances in the serum of immunized animals were demonstrated by absorption tests to consist of specific and group agglutinins in cases in which the agglutinins were sufficiently developed to make use of this method. 4. The pneumococci seem to show marked differences in their ability to undergo agglutination. 5. There was considerable uniformity of reaction of the various strains in low dilutions, but this uniformity is not continued as the animal becomes more highly immunized. 6. At present it is not possible to establish a definite relation between the agglutination reaction and the other characteristics of the pneumococcus, except in the case of the *Pneumococcus mucosus*.

32. **Bacteria Found in Mouth and Lungs After Death.**—The studies made by Norris and Pappenheimer were confined to a determination of the prevalence of the pneumococcus in normal lungs and in lungs which presented various lesions. The report embodies the results of the bacterial examination of 42 human lungs. The cases were taken at random and included patients dying outside of the hospital, patients dying in the hospital within 24 hours after admission and patients dying 24 hours or longer after admission. The lungs were selected from subjects examined within 24 hours after death. The authors found that organisms of the pneumococcus or streptococcus group were present in the lungs of practically all cases, whether normal or showing a variety of lesions; strictly speaking, they were found in forty out of forty-two cases, or in 95 per cent. of the series. The pneumococci and the streptococci were obtained in practically similar percentages—that is, 50 per cent. of the cases. Pneumococci were obtained more frequently in the small series of patients exposed for some time to hospital atmosphere. The number of cases examined, however, was insufficient, and the findings may thus be accidental, and hence of no value. Test micro-organisms, namely, small portions—half a dram or less—of *Bacillus prodigious*

introduced into the human mouth after death were conveyed to and recovered from the lungs by culture in a little over half of the cases in which this experiment was tried. The test micro-organisms are probably conveyed to the lungs with the fluid which collects just before death. The numerous manipulations entailed in the removal of the body from the wards to the morgue greatly facilitate the entrance of any fluid from the pharynx and buccal cavity into the lungs. It follows, logically, from the results obtained in this experiment, that the cultural findings after death are not a guide to the bacterial contents of the lungs during life, and that any deductions made from such findings are unreliable and deceptive. There is every reason to believe that any of the micro-organisms present in the mouths and pharynx, and, in many cases, in the stomach contents, may enter the lungs, and, if conditions be suitable, increase in numbers, during the time between death and the examination of the lungs. There exists, perhaps, more frequently than has hitherto been suspected, a series of diplococci, intermediate between the typical pneumococci and streptococci. The diplococci of this type were found in 40 per cent. of the cases examined. The differential diagnosis of these atypical diplococci from the pneumococci and streptococci is a difficult one, depending, as it does, on general cultural characteristics. No single character, such as the presence of capsules or the fermentation of inulin, virulence, etc., has been found to be a certain criterion. The agglutinative reactions made seem to show that these intermediate diplococci have none or only slight agglutinative affinities to the typical pneumococcus. Further tests must be made, however, with the various methods at hand before this statement can be accepted as final. These diplococci are of interest from the fact that they have been found in the blood during life, and in the pial exudate in cases of meningitis, endocarditis, etc. These studies throw no light whatever on the conditions which determine the onset of lobar pneumonia in apparently healthy persons. Moreover, the authors were unable to draw conclusions as to the presence of pneumococci in the lungs during life, or as to the channels by which they gain access thereto.

35. **Comparative Study of Pneumococci and Allied Germs.**—The investigations in this field of work made by Hiss lead to the following conclusions: (a) Organisms, not to be distinguished by morphologic characters or by any physiologic peculiarities from true pneumococci derived from pathologic sources, occur with frequency in the mouths of healthy persons and those suffering from slight inflammations of the nasopharynx, and the only permissible and legitimate conclusion is that these organisms are true pneumococci. (b) There are other organisms in normal mouths and from pathologic sources that morphologically or by staining reactions are not definitely to be distinguished from pneumococci, and can only be recognized by a careful study of their fermentative activities and agglutination reactions. These organisms are non-inulin fermenters. (c) The organism known as *Streptococcus mucosus* is at times found in cultivations from the mouths of apparently healthy individuals, and that, although it shows certain peculiarities distinguishing it from the typical pneumococcus, it is probably very closely related to, and a variety of, this species. (d) Other organisms occur which in their fermentation are indistinguishable from pneumococci, but which enter morphologically or in agglutination reactions show a variation from this type. Some of these are probably temporarily or permanently modified pneumococci or *Streptococcus mucosus*; others, it may be, are streptococci of types which it has not heretofore been possible to recognize and describe. Some of these organisms were isolated from pneumonic lungs at autopsy, or from some internal source, such as the circulating blood, and presumably have long resided under conditions which may be considered adverse, thus bringing about a modification of their morphology or physiology. This theory is supported by the observation that pneumococci from such sources—perfectly typical morphologically and in fermentative articles—are apt to show a lessening of their ability to agglutinate.

36. **Viability of Pneumococcus.**—According to Wood, the life of the pneumococcus in moist sputum is of considerable duration, the average period being less than two weeks unless the material is exposed to direct sunlight. As such sputum, however, does not give off bacteria even when exposed to strong currents of air, it may be considered as innocuous except to persons handling clothes, bedding, etc., which have recently been contaminated. Under ordinary conditions this sputum dries in the course of a few hours or days. The dried masses retain their virulence for a long time, and if deposited on the floor or on the bedding of the patient may be powdered mechanically, and sweeping, dusting, or brushing the contaminated articles will distribute pneumococci in the air. Fortunately the organisms in the sputum do not remain long in suspension and die off rapidly under the action of light and desiccation. In sunlight or in diffuse daylight the bacteria in such powder die within an hour, and in about four hours if kept in the dark. The danger of infection from powdered sputum, therefore, may be avoided by ample illumination and ventilation of the sickroom in order to destroy or to dilute the bacteria, and by the avoidance of dry sweeping or dusting. Articles which may be contaminated and which can not be cleaned by cloths dampened in a suitable disinfectant should be removed from the patient's vicinity. When a person suffering from a pneumococcus infection coughs, sneezes, expectorates, or talks, particles of sputum or saliva, which may contain virulent pneumococci, are expelled from the mouth. Such particles remain suspended in the air for a number of hours if the ventilation of the room is good. They may be inhaled by persons in the vicinity of the patient, or they may be deposited on various articles in the room. Wood's studies show that, whether suspended in the air or dried on surrounding objects, these micro-organisms become harmless in a very short time, about an hour and a half being the extreme limit, while many of the pneumococci in the spray perish in a few minutes, especially if exposed to strong light. In the light of these experiments, the risk of infection from the pneumococcus is largely confined to those in direct contact with the person whose excreta contain the organism.

38 *Immediate Mortality in Abdominal Section, Based on a Personal Experience in 2,008 Cases. G. W. Crile, Cleveland.
39 Case of Traumatic Asphyxia. R. H. Birge, Cleveland.
40 Significance of Pathologic Elements in the Urine, with a Desciption of the Best Methods of Ascertaining Their Source. W. E. Lower, Cleveland.
41 X-Ray Treatment of Skin Diseases a "Passing Fad." W. I. LeFevre, Cleveland.

38. **Mortality in Abdominal Section.**—Crile details his experience in 2,008 cases of abdominal section. The gastrointestinal tract was operated on 894 times, 748 times for appendicitis, with 72 deaths, a mortality of 8.05 per cent. The genitourinary tract was the site of operation 121 times, 41 times for floating liver, with 11 deaths, a mortality of 8.3 per cent. The pelvic organs were operated on 751 times (including five Cesarean sections), with 13 deaths, a mortality of 1.7 per cent. The liver and gall bladder were operated on 130 times, with 11 deaths, a mortality of 8.3 per cent. There were 45 cases of ventral hernia, with 1 death, a mortality of 2.22 per cent., and 65 miscellaneous operations, with 5 deaths, a mortality of 7.6 per cent. The total mortality for the 2,008 cases was 5.2 per cent. In 74 cases, death was due to infection. This does not mean infection following operation in a clean field, but it means that patients with acute peritonitis, general peritonitis, ruptured gall bladder, perforation of the stomach and of the intestines, acute infection following miscarriages and abortions, had gone past medical treatment and operation was done with the hope of controlling or arresting the process. In 12 cases, death was due to exhaustion. These were principally cases of inoperable malignant tumors; in some only cocain incision was made and the inoperability of the tumor established. In several cases of long-continued exhausting infection with multiple abscesses, the patients died of exhaustion. The larger number of the 12 cases in this list occurred in the early years before the great importance of not permitting the patient in an operable case to remain in the

recumbent posture during the repair of the wound was realized. There were no cases of death from shock *per se*, but there were 10 cases in which the infection existing at the time of operation, and its continuation, together with the shock of the operation, caused death. Emboli and thrombosis were fatal in four cases, three of pulmonary embolism, and one involving the mesenteric artery. The latter patient was supposed to have died of obstruction of the bowels. At autopsy it was found that embolism was the cause of death, the obstruction being secondary. In four instances, pneumonia caused death, in two of which, although it was not proved, Crile felt quite certain that septic emboli were the exciting cause. The other two were cases of bronchopneumonia, vaguely termed ether pneumonia. In one case death was due to complete suppression of urine. Obstruction of the bowels *per se* is not mentioned as having in a single instance caused death. Of this total number of cases, 736 were operated on for relief from infection; that is to say, were infective cases. Of these, the mortality rate was 11 per cent. The greatest risk lies in visceral perforation, typhoid perforation, gastric duodenal ulcer, and gunshot wounds. In 160 malignant tumors treated surgically the risk was 11 per cent. There were 1,108 noninfective cases, with five deaths, a mortality of 4 per cent.

45. **Tent in Tuberculosis.**—Pettit discusses the value of the tent in the treatment of tuberculosis, and points out the advantages of the tent as compared with confining patients in rooms. He says that from an economic standpoint the tent commends itself. The housing of tuberculous patients in buildings is not only unnecessary, but it is in violation of an essential principle which has for its object providing the patient with fresh air. The only argument that can reasonably be deduced for placing patients in buildings is that it is necessary to keep them warm. A tent with necessary furnishings is far cheaper, more rational and more conducive to securing the favorable outcome. Tuberculous patients need not be housed in substantial buildings in order to make them comfortable.

52. **Unusually Large Ureteral Calculus.**—Bovée removed an unusually large ureteral calculus transperitoneally. The calculus measured 2¾ by 1¾ by 1½ inches and weighed 1,310 grains. It was kidney-shaped, one end larger than the other, was grayish in color and had rough surfaces. On section it was found to consist of several concentric layers of phosphatic formation covering over a decidedly dark mass one inch in diameter, which contained many layers composed of a deposit of calcium oxalate.

53. **Transposition of Viscera.**—In the first case reported by Randolph and Thomas the heart, liver and stomach were transposed, but were normal in size. An interesting feature of this case is the fact that the maternal grandfather (the second case) of this patient presents the same phenomena, the heart, liver and spleen being transposed.

59. **Surgery of Abortions.**—The operation suggested by Fortner consists essentially of obliterating the lumen of the Fallopian tubes in cases in which it is impossible or undesirable that the patient shall again conceive. It is performed as follows: The abdomen is entered by the median suprapubic method; the fundus uteri and tube are brought to the surface; the peritoneum overlying the contracted portion of the tube half an inch, or slightly more, from the uterus, is caught up and snipped longitudinally with scissors between tissue forceps; a silk-threaded artery needle is passed through this slit, around and under the tube which is looped up as is the cord in a Bassini hernia operation; the ligature is tied only sufficiently snug to hold without damage; the tube is cut off and its distal end pulled into a second loop of the same ligature, which is tied and dropped back into the peritoneal slit, which, in turn, is closed by two or three running catgut sutures, and the operation is completed, except closing the abdomen in the usual way. The hemorrhage amounts to little more than a stain. Fortner says that this operation goes beautifully with that of fixation in cases in which the woman has acquired a displaced uterus and the incurable habit of aborting, as is found in the best of women. Some of the results of the procedure are: No more conceptions; the distorted, sorely afflicted, suffering bladder and other pelvic organs, with rest, resume their normal condition and function; no more distal tubal or ovarian infections; no more depressing, neurosis-producing apprehensions; no adhesions.

2. **Effects of Ether on Renal Activity.**—The investigations made by the two Pringles and by Maunsell were undertaken with the object of determining clinically the influence of ether anesthesia on the secretion of urine. The method adopted was to take periods before, during and after the anesthesia, as follows: Period 1. Twenty-four hours, ending at 9 a. m. on morning of operation. Period 2. From 9 a. m. on the morning of operation till immediately preceding the administration of the anesthetic. Period 3. During the induction of anesthesia, ending with the abolition of corneal reflex. Period 4. First half-hour of complete anesthesia. Period 5. Second half-hour of complete anesthesia. Period 6. Third half-hour of complete anesthesia. Period 7. Six hours following anesthesia. Period 8. Twenty-four hours following Period 7. The bladder was emptied by catheter at the end of each period. Examinations were made in 10 cases. The ages of the patients ranged from 18 to 50. The operations done on them included myomectomy, ovariotomy, curettement, appendicectomy, excision of varicose veins, and removal of cervical glands. Period 1 was taken as the normal rate of secretion. Period 2 showed an increase in every case except one, the increase being accounted for by the nervous condition of the patient preceding operation. In Period 3 the secretion was increased in some cases and decreased in others. In Period 4 the effect of full anesthesia became evident, every case showing a great decrease, the average rate of secretion being only 23 per cent. above the normal. In Period 5 there was a further decrease, the average being only 55 per cent. of Period 6 and 13 per cent. of Period 1. In each of the two cases in which the anesthetic was continued for Period 6, the rate showed a further decrease. In Period 7 the rate of secretion rose, but never reached the normal, as indicated in Period 1. In Period 8 a slight decrease in the rate of secretion was seen in every case. In the majority of cases this decrease seemed to have no definite relation to either the amount of fluid taken or to the amount vomited during the thirty hours following operation. During the time of full anesthesia the excretion of the nitrogenous constituents of the urine was diminished to such an extent as to amount to practical suppression. This condition appears to increase the longer the anesthetic is continued. Furthermore, the kidney substance apparently recovers its power of secretion of water after the removal of the anesthetic more rapidly than it regains its power of nitrogenous excretion.

3. **Hemolytic and Hemosozic Serums.**—Ruffer and Crendiropoula summarize the results of their experiments as follows: 1. Bile contains at least two hemolysins or groups of hemolysins: (1) biliary hemolysin No. 1 (insoluble in alcohol), which produces a hemosozic serum when injected into rabbits; and (2) biliary hemolysin No. 2, which produces no hemosozic serum when injected. 2. Bile contains a hemosozic precipitate which, when injected into rabbits, produces a hemolytic serum. 3. The hemosozic precipitate added to bile never prevents completely the hemolysis produced by the bile. 4. The hemosozic precipitate neutralizes the hemolysin insoluble in alcohol (hemolysin No. 1), but not the hemolysins soluble in alcohol (hemolysin No. 2). 5. The hemosozic precipitate prevents the hemolytic action of a serum produced by the injection of bile.

4. **Empyema of the Gall Bladder.**—In the case reported by Stoney there was an empyema of the gall bladder, the result of the obstruction of the commencement of the cystic duct by calculus. Owing to the fact that the liver was enlarged so that the anterior edge, which was very thin, reached almost to the level of the umbilicus, though a dull note on percussion was only obtained for one and one-half inch below the costal

margin, the tumor was situated below the level of the umbilicus. In addition to this, the transverse colon was adherent to the under surface of the liver between its anterior sharp margin and the fundus of the gall bladder, causing a resonant note to be obtained on percussion between the hepatic dullness above and the gall bladder dullness below. As the result of these two factors a wrong diagnosis of appendicitis was made.

23 Case of Pneumonic Plague. H. B. Osburn.

17. **Treatment of Eclampsia.**—If the attack can not be warded off, Byers recommends the following method of treatment: "1. Treat the convulsions with morphin used subcutaneously. Keep the patient on her side, purge freely, use saline infusion, allow no liquids; in a word, as Gooch advised long ago, 'take care of the convulsions, and let the uterus take care of itself.' 2. Make an effort to eliminate the poison by purgation, hot packs and by saline infusion. 3. If labor has not set in, treat the convulsions, but do not induce premature action of the uterus. If labor has begun and the patient is in the second stage and the os dilated, give chloroform and deliver by forceps, if possible, or by turning. If, however, morphin and purgation with saline injections have been tried and the patient is not improving, dilate the cervix and deliver. 4. For the convulsions after delivery use morphin, purgatives and saline infusion. 5. In the prophylaxis of eclampsia rest, milk diet, warm baths and purgatives are the best methods of treatment."

19. **Appendicitis.**—Thomas has done 129 consecutive and successful Treves operations for appendicitis during the quiescent period. He advises removal of the appendix in cases of operation for ventral hernia following the opening of a perityphlitic abscess, and in cases of persistent thickening or induration after a first attack of appendicitis, and after two definite inflammatory attacks. The questions of diagnosis and operations are also discussed.

32. **Infectious Gastroenteritis.**—Pottevin reports several new points of resemblance between the *B. enteriditis*, the paratyphoid and the hog cholera bacillus, and the H. bacillus. He accepts them as belonging to a group which he calls the Salmonella. In case of epidemics or epizootics, of a gastrointestinal character, more attention should be paid to the domestic animals as sheltering the germs. Many clinical cases of paratyphoid infection from cattle have probably been diagnosed as typhoid fever. Sheltered by the animal, the germs have been scattered in its dung, entailing infection of man in the rural districts; it may be transmitted to the city in milk, meat, vegetables or otherwise.

34. **Typhoid and Plague Vaccination.**—Besredka reports research on rabbits in the line of vaccination by means of an endotoxin and its antiendotoxin, both for typhoid fever and plague.

35. **Operative Injury of Thoracic Duct.**—Vautrin has observed 4 cases of operative injury of the thoracic duct during an operation. The results were insignificant in three of the cases, but in the other they were so serious that he writes this article to protest against the optimism which prevails in regard to injuries of this nature. He reviews the various methods of caring for such an injury in vogue, preferring, himself, to ligate the vessel after exposing it and testing the condition of its walls. This ligature may prove very difficult when the duct has to be sought behind the blood vessels, in the retrosternal region. This should be done at once, instead of waiting until the patient has become so much debilitated from the loss of lymph from the duct that he is scarcely able to bear any surgical intervention. In his fatal case the patient had had congestion of the lungs, dyspnea and tachycardia on previous occasions, which made him hesitate to resort to general anesthesia and to ligate the thoracic duct when it could have been done on the exposed, easily accessible portion. When he was finally compelled to this course, ligation was no longer possible except at a more inaccessible part of the duct, rendering the operation so grave that the patient finally succumbed. He advises ligature from the first, without wasting time on compression, if the walls of the duct are not too friable. It is a dangerous procedure in case of the absence of collaterals. When both these conditions are encountered the prognosis is necessarily bad.

38. **Danger from Illuminating Gas During Chloroform Anesthesia.**—Armand and Bertier state that the combustion of illuminating gas in a close room in which chloroform is being administered produces toxic gases rapidly fatal in sufficient quantity to birds and mammals. These gases reveal their presence by a whitish vapor, irritating to the mucosa and causing coughing, even in small amounts, and actually dangerous when the room is small and imperfectly ventilated. Certain individuals are more susceptible than others to the action of these irritating gases, and it is possible for the patient on the operating table to feel their effect more intensely than the surgeon or his aids, while, owing to the anesthesia, intoxication may occur without its onset being suggested by any symptoms until cyanosis and the respiratory syncope are noticed. The toxic gas generated is chloro-oxy-carbonic acid. It has a specific poisonous action on the blood. Armand is convinced that a number of "chloroform deaths" have been due to this cause.

39. **Treatment of Arteriovenous Aneurism of the Subclavian.**—Pluyette and Bruneau review the cases on record of operative treatment of subclavian aneurism. They are few in number and the results were far from encouraging. Three died out of the 7 patients operated on, while only 1 died among 12 patients not operated on. Of the 4 who survived the operation, 2 were left with functional impotence and the others were lost to sight immediately after. Expectant treatment seems preferable, they think, although menacing hemorrhage or other indication may force the surgeon's hand.

41. **Tuberculous Stenosis of the Pylorus.**—Ricard and Chevrier conclude this extensive study of tuberculosis of the pylorus with an account of two patients treated by gastroenterostomy. This brings the total number of authentic cases on record to

16. Gastroenterostomy has been done six times. It has the advantage, they think, over all other measures for the relief of this condition. It does not touch the focus, but leaves it in repose, and offers the most favorable conditions for its healing. Gastroduodenostomy would be the ideal physiologic technic, but it is more difficult, and practice is worth more than theory in such cases. They advocate posterior, transmesocolic gastroenterostomy.

42. **Abdominoperineal Amputation of Rectum.**—Goullioud and Faysse comment on the greater danger of this operation in men than in women. Out of 31 cases in which this operation was performed, there were 11 deaths and 20 recoveries, but only 5 of the 15 men recovered, while all but 1 of the 16 women made an uneventful recovery. The mortality for the men was, therefore, 66.6 per cent., while it was only 6.2 per cent. for the women. One reason for this difference may be the closer connection between the urinary passages and the rectum in man. Once accepting the sacrifice of the sphincters, the abdominoperineal operation along the lines laid down by Quénu is a notable progress in the treatment of cancer of the rectum. It permits the removal of otherwise inoperable neoplasms.

43. **Gastric Ulcer.**—Wirsing relates comparative trials of the Lenhartz and von Leube-Ziemssen dietetic treatments of gastric ulcer. The Lenhartz technic has been described by Wagner, and was summarized in The Journal, Feb. 13, 1904, page 495. Wirsing found it distinctly superior to the other technics in cases of gastric ulcer with hemorrhage. It supplies more nourishment, and although it irritates the ulcer more than other technics, the advantages of more nourishment for the subjects debilitated by the hemorrhages, outbalance the local action on the ulcer. On the other hand, the von Leube-Ziemssen technic gave much better results in the cases without hemorrhage and consequent anemia. Wirsing's article is based on 320 cases of gastric ulcer. Only one-sixth of the patients were men. The Lenhartz method was followed in 42 cases, in half of which hemorrhage had been observed. The patients were given two raw whipped eggs and 20 c.c. of milk the first day, ice cold, increasing daily by one egg and 100 c.c. milk until they were taking eight eggs and one liter of milk during the twenty-four hours. After the sixth day chopped meat, butter, etc., are allowed in progressive amounts. Ice was applied to the stomach during the first seven to ten days in case of recent hemorrhages, and from 1 to 2 gm. of bismuth were given three times a day, sometimes with extract of bell. When there were no further pains, liq. ferr. alb. was administered, with Fowler's solution in case of severe anemia. The patients were kept in bed for from two to four weeks. Only a few patients found this diet disagreeable and the albumin had to be given in another form. The acidity approximated normal in the course of this treatment and all the patients gained in weight, but not to the extent of Wagner's patients, who averaged nearly 20 pounds. A circular of inquiry was sent to all the 320 patients who had been treated in the hospital, asking for details in regard to their present state of health, and answers were received from 108. They showed that 68 per cent. of the hemorrhagic patients had been permanently cured, and 53 per cent. of the non-hemorrhagic. It is possible that the hemorrhage provides more favorable conditions for the healing of the ulcer. Hematemesis had not occurred in any case in which there had been no hemorrhage before treatment. Sixty-seven of the patients stated that the ulcer had not been cured or had recurred, but as only 21 of these had sought medical aid later, it is evident that the troubles could not have been very serious. A number of other points are brought out in Wirsing's communication. Among them is the difficulty of diagnosing gastric ulcer, even when it is approaching perforation. Fifty-two of the patients had no pains. In others the pains did not correspond to the location of the ulcer, but were in the solar plexus or the pylorus. The painful point in the back to the left, near from the seventh to the tenth dorsal vertebræ, which Boas has found in one-third of all his cases, was noted in about half of Wirsing's patients. Pains in change of position were observed in one-third of all cases. Vomiting during the three hours after eating had occurred in 59 per cent. of all the cases. Hemorrhage was much more frequent among the male patients. In 3 cases the hemorrhage was the first symptom noted. Perforation occurred in four instances and immediate intervention saved two of the patients. In a fifth case the diagnosis had been merely acute gastritis. In the others the perforation was the first sign of serious trouble, occurring in one patient after a dance. In a fifth case the patient was not seen until nearly twelve hours after the perforation in a fasting stomach. As she seemed to be doing well no operation was attempted and she recovered.

44. **Treatment of Ischochymia (Ectasia of Stomach).**—See The Journal, June 17, 1905, page 1962.

45. **Quantitative Tests of Products of Putrefaction and Fermentation in the Feces.**—Ury has been studying this subject for four years and published his results last spring in the *Deutsche med. Wochft.*, No. 19. He here further elaborates them and describes his technic in detail. His aim is to establish the normal standards for the feces in every respect, which he thinks he has accomplished in some directions. When normal standards are once known then the pathologic variations can be easily studied.

Berliner klinische Wochenschrift.

47 (XLII, No. 33, Aug. 14.) *Zur Operation der Tumoren des Kleinhirn-Brückenwinkels (cerebellum-pons angle). M. Borchardt.
48 *Interruption of Pregnancy on Account of Tuberculosis or Vomiting.—Ueber die künstliche Unterbrechung des Schwangerschaft wegen starken Erbrechens und Schwindsucht. P. Ruge.

53 *Zur Diagnostik des Magenchemismus. V. Bartenstein.
54 Prophylaxe und Abortiv-Behandlung der Gonorrhœ. J. Vogel.

47. **Tumors in Cerebellar-Pons Angle.**—Borchardt describes a case of fibrosarcoma in the angle between cerebellum and pons, which was removed without much trouble. The patient died the following day, probably from the effects of compression by coagula left from two preceding ineffectual attempts to reach the tumor, interrupted on account of severe hemorrhage and the extreme weakness of the patient. The conditions of successful removal of a tumor at this point are a good constitution on the part of the patient, distinct encapsulation of the tumor, which must not be too deeply situated, and absence of much hemorrhage. If the tumor had been a cyst or cholesteatoma the extirpation would probably have been successful. Intervention should be prompt, before loss of vision. The symptoms in the case described had been headache, vomiting, vertigo, uncertain gait, choked disc, attacks of apathy and trismus, deviation of head, slight acceleration of pulse, subjective sounds in the ears, etc.

48. **Artificial Interruption of Pregnancy in Tuberculosis and Uncontrollable Vomiting.**—Ruge summarizes his views in the statement that in advanced cases of tuberculosis, the interests of the child should be regarded as paramount, while in incipient tuberculosis the interests of the mother should take precedence. In case of uncontrollable vomiting the general condition is the criterion as to whether to interfere or not. If in spite of emaciation the patient still feels well and strong, the pregnancy should not be disturbed, but when loss of strength becomes apparent, consideration for the child, he thinks, should yield to the mother's interests.

50. **Intoxication from External Use of Resorcin.**—A man of 29 was treated with applications of a 50 per cent. resorcin paste on account of lupus, about 100 gm. of the paste being rub-

bed into the two patches. In a few minutes he began to exhibit symptoms like those noted when resorcin has been taken internally, convulsions, lethargy, etc. Consciousness was not regained for an hour or more, but recovery was complete by the fourth day.

51. **Stomach Secretions in Gynecologic Affections.**—Winkler found evidences of hypochlorhydria in all his severer gynecologic cases. The measures directed against the gynecologic affection had to be supplemented by treatment of the subacidity. He thinks that subacidity should be assumed and treated in all gynecologic cases, in the absence of evidence to the contrary. Displacement of the genital organs and of the stomach is probably the result of a single cause, and motor insufficiency generally accompanies the gastroptosis which he noted in 18 out of 31 gynecologic patients examined. He tabulates 41 gynecologic cases, free from any stomach affection, in which he noted secretory anomalies in the majority, and almost invariably in the line of subacidity.

53. **Chemistry of Stomach.**—Bartenstein points out a source of error in chemical examinations of the stomach. He has found that the stomach contents do not form a homogeneous mass, but that the acidity of different portions varies within wide limits. The total acidity of the stomach contents—as mixed in a jar after withdrawal—may be only 60, when in reality it may be 90 in some parts of the stomach and 30 in others. The hyperacid regions may react with the symptoms of hyperchlorhydria, when chemical tests in the jar would seem to exclude such a condition of hyperacidity. Tests based on examination of only a small portion of the stomach contents are liable to give erroneous conclusions.

55. **Nervous Gastrointestinal Affections.**—Boas groups nervous gastrointestinal affections as those with a single or with several symptoms. The single symptoms may vary from time to time, but this group is much more easily diagnosed than the cases with several symptoms. Besides the anamnesis, the course of the affection is important for diagnosing, the striking, motiveless intermissions and leaps and the absolute independence between the disturbances and the diet, while the disturbances are dependent to the last degree on emotions, overexertion, changes of air, etc. The physician, not the medicine, is what cures in these cases. A change of environment is one of the most important measures, but scarcely less important is the principle gradually to spur the sound but irritable digestive tract to maximal work. Most of these nervous gastrointestinal affections lead to under-nourishment of the individual. Institution treatment is almost indispensable, and after dismissal the patients must be warned to keep away from business for several months and to continue the diet found most suitable. They should keep watch of their weight every week, and whenever it begins to go down, another brief course of dietetic treatment should be commenced to regain what is lost. Electrotherapy, massage, hydrotherapy and movements are frequently applied without individualizing, so that the full benefit is not derived from them. Local procedures have never done much good in his experience, with the exception of faradization of the rectum, which he has found invaluable in habitual obstipation from atony. Fashionable watering places are contraindicated for nervous gastrointestinal troubles; such patients require quiet and freedom from strain. Drugs should not be given much, as these patients should be taught that hygiene and a regular and rational mode of life are the main factors in getting and keeping well.

57. **Fetal Heart Sounds Audible at Thirteenth Week.**—Sarwey reiterates his former assertions in regard to the possibility of auscultating the fetal heart sounds from the thirteenth week of the pregnancy. They become perceptible almost always at the same spot in the horizontal plane of the internal os. The conditions for successful auscultation are a trained ear, a perfectly quiet room, great patience on the part of the examiner, preliminary complete emptying of the bladder with the catheter, and approximation of the anterior wall of the uterus to the anterior abdominal wall, which must be pushed in deep with the stethoscope, just back of the symphysis.

70. **Immunization Treatment of Pulmonary Tuberculosis with Bovine Tuberculin.**—Spengler's previous communications on the immunization treatment of tuberculous subjects with tuberculin made from bovine material have been summarized in these columns as published. He here reports the particulars of the agglutinating property acquired in 80 cases of tuberculosis in which the patients had been immunized with his perlsucht tuberculin. Koch found agglutination at 1-25 and 1-75 in 51 out of 74 cases treated with his tuberculin, the majority of the rest agglutinating at 1-75 to 1-300. Spengler with his perlsucht tuberculin found agglutination from 1-300 to 1-3,000 in 60 out of the 80 subjects, and from 1-100 to 1-300 in the rest. The most rapid increase in the agglutinating property and the most intense bactericidal action were noted in patients under treatment with the tuberculin when the edematous-inflammatory reaction at the point of injection was allowed to subside completely before another injection was attempted. This is especially important for avoidance of organ reactions in case of tuberculous nephritis, pseudoasthma and in tuberculosis of intestines, larynx or ears. He found the systematic administration of iodin useful in promoting the formation of agglutinins. All the patients with tuberculosis in whom the disease dated from youth made much better progress in agglutination and curative properties when supplemented by the use of iodin. Lues in all its manifestations has an inhibiting influence on the increase of the agglutinating properties, as also severe physical or intellectual work. General hygienic measures and mode of life favor the acquirement of agglutinating properties, while depressing circumstances, weak heart, underfeeding and overworking act against it. A small number of tuberculous and phthisic patients were unable to tolerate the perlsucht tuberculin, the infection in their case being probably of bovine tuberculosis origin. Spengler adds, in conclusion, that he supplies his perlsucht tuberculin only to those physicians who have had special training in the specific treatment of tuberculosis. He agrees with Petruschky that the introduction of tuberculin treatment requires special training beforehand.

16. Gastroenterostomy has been done six times. It has the advantage, they think, over all other measures for the relief of this condition. It does not touch the focus, but leaves it in repose, and offers the most favorable conditions for its healing. Gastroduodenostomy would be the ideal physiologic technic, but it is more difficult, and practice is worth more than theory in such cases. They advocate posterior, transmesocolic gastroenterostomy.

42. **Abdominoperineal Amputation of Rectum.**—Goullioud and Faysse comment on the greater danger of this operation in men than in women. Out of 31 cases in which this operation was performed, there were 11 deaths and 20 recoveries, but only 5 of the 15 men recovered, while all but 1 of the 16 women made an uneventful recovery. The mortality for the men was, therefore, 66.6 per cent., while it was only 6.2 per cent. for the women. One reason for this difference may be the closer connection between the urinary passages and the rectum in man. Once accepting the sacrifice of the sphincters, the abdominoperineal operation along the lines laid down by Quénu is a notable progress in the treatment of cancer of the rectum. It permits the removal of otherwise inoperable neoplasms.

43. **Gastric Ulcer.**—Wirsing relates comparative trials of the Lenhartz and von Leube-Ziemssen dietetic treatments of gastric ulcer. The Lenhartz technic has been described by Wagner, and was summarized in The Journal, Feb. 13, 1904, page 495. Wirsing found it distinctly superior to the other technics in cases of gastric ulcer with hemorrhage. It supplies more nourishment, and although it irritates the ulcer more than other technics, the advantages of more nourishment for the subjects debilitated by the hemorrhages, outbalance the local action on the ulcer. On the other hand, the von Leube-Ziemssen technic gave much better results in the cases without hemorrhage and consequent anemia. Wirsing's article is based on 320 cases of gastric ulcer. Only one-sixth of the patients were men. The Lenhartz method was followed in 42 cases, in half of which hemorrhage had been observed. The patients were given two raw whipped eggs and 20 c.c. of milk the first day, ice cold, increasing daily by one egg and 100 c.c. milk until they were taking eight eggs and one liter of milk during the twenty-four hours. After the sixth day chopped meat, butter, etc., are allowed in progressive amounts. Ice was applied to the stomach during the first seven to ten days in case of recent hemorrhages, and from 1 to 2 gm. of bismuth were given three times a day, sometimes with extract of bell. When there were no further pains, liq. ferr. alb. was administered, with Fowler's solution in case of severe anemia. The patients were kept in bed for from two to four weeks. Only a few patients found this diet disagreeable and the albumin had to be given in another form. The acidity approximated normal in the course of this treatment and all the patients gained in weight, but not to the extent of Wagner's patients, who averaged nearly 20 pounds. A circular of inquiry was sent to all the 320 patients who had been treated in the hospital, asking for details in regard to their present state of health, and answers were received from 108. They showed that 68 per cent. of the hemorrhagic patients had been permanently cured, and 53 per cent. of the non-hemorrhagic. It is possible that the hemorrhage provides more favorable conditions for the healing of the ulcer. Hematemesis had not occurred in any case in which there had been no hemorrhage before treatment. Sixty-seven of the patients stated that the ulcer had not been cured or had recurred, but as only 21 of these had sought medical aid later, it is evident that the troubles could not have been very serious. A number of other points are brought out in Wirsing's communication. Among them is the difficulty of diagnosing gastric ulcer, even when it is approaching perforation. Fifty-two of the patients had no pains. In others the pains did not correspond to the location of the ulcer, but were in the solar plexus or the pylorus. The painful point in the back to the left, near from the seventh to the tenth dorsal vertebræ, which Boas has found in one-third of all his cases, was noted in about half of Wirsing's patients. Pains in change of position were observed in one-third of all cases. Vomiting during the three hours after eating had occurred in 59 per cent. of all the cases. Hemorrhage was much more frequent among the male patients. In 3 cases the hemorrhage was the first symptom noted. Perforation occurred in four instances and immediate intervention saved two of the patients. In a fifth case the diagnosis had been merely acute gastritis. In the others the perforation was the first sign of serious trouble, occurring in one patient after a dance. In a fifth case the patient was not seen until nearly twelve hours after the perforation in a fasting stomach. As she seemed to be doing well no operation was attempted and she recovered.

45. **Quantitative Tests of Products of Putrefaction and Fermentation in the Feces.**—Ury has been studying this subject for four years and published his results last spring in the *Deutsche med. Wochft.*, No. 19. He here further elaborates them and describes his technic in detail. His aim is to establish the normal standards for the feces in every respect, which he thinks he has accomplished in some directions. When normal standards are once known then the pathologic variations can be easily studied.

55. Nervous Gastrointestinal Affections.—Boas groups nervous gastrointestinal affections as those with a single or with several symptoms. The single symptoms may vary from time to time, but this group is much more easily diagnosed than the cases with several symptoms. Besides the anamnesis, the course of the affection is important for diagnosing, the striking, motiveless intermissions and leaps and the absolute independence between the disturbances and the diet, while the disturbances are dependent to the last degree on emotions, overexertion, changes of air, etc. The physician, not the medicine, is what cures in these cases. A change of environment is one of the most important measures, but scarcely less important is the principle gradually to spur the sound but irritable digestive tract to maximal work. Most of these nervous gastrointestinal affections lead to under-nourishment of the individual. Institution treatment is almost indispensable, and after dismissal the patients must be warned to keep away from business for several months and to continue the diet found most suitable. They should keep watch of their weight every week, and whenever it begins to go down, another brief course of dietetic treatment should be commenced to regain what is lost. Electrotherapy, massage, hydrotherapy and movements are frequently applied without individualizing, so that the full benefit is not derived from them. Local procedures have never done much good in his experience, with the exception of faradization of the rectum, which he has found invaluable in habitual obstipation from atony. Fashionable watering places are contraindicated for nervous gastrointestinal troubles; such patients require quiet and freedom from strain. Drugs should not be given much, as these patients should be taught that hygiene and a regular and rational mode of life are the main factors in getting and keeping well.

57. Fetal Heart Sounds Audible at Thirteenth Week.—Sarwey reiterates his former assertions in regard to the possibility of auscultating the fetal heart sounds from the thirteenth week of the pregnancy. They become perceptible almost always at the same spot in the horizontal plane of the internal os. The conditions for successful auscultation are a trained ear, a perfectly quiet room, great patience on the part of the examiner, preliminary complete emptying of the bladder with the catheter, and approximation of the anterior wall of the uterus to the anterior abdominal wall, which must be pushed in deep with the stethoscope, just back of the symphysis.

70. Immunization Treatment of Pulmonary Tuberculosis with Bovine Tuberculin.—Spengler's previous communications on the immunization treatment of tuberculous subjects with tuberculin made from bovine material have been summarized in these columns as published. He here reports the particulars of the agglutinating property acquired in 80 cases of tuberculosis in which the patients had been immunized with his perlsucht tuberculin. Koch found agglutination at 1-25 and 1-75 in 51 out of 74 cases treated with his tuberculin, the majority of the rest agglutinating at 1-75 to 1-300. Spengler with his perlsucht tuberculin found agglutination from 1-300 to 1-3,000 in 60 out of the 80 subjects, and from 1-100 to 1-300 in the rest. The most rapid increase in the agglutinating property and the most intense bactericidal action were noted in patients under treatment with the tuberculin when the edematous-inflammatory reaction at the point of injection was allowed to subside completely before another injection was attempted. This is especially important for avoidance of organ reactions in case of tuberculous nephritis, pseudo-asthma and in tuberculosis of intestines, larynx or ears. He found the systematic administration of iodin useful in promoting the formation of agglutinins. All the patients with tuberculosis in whom the disease dated from youth made much better progress in agglutination and curative properties when supplemented by the use of iodin. Lues in all its manifestations has an inhibiting influence on the increase of the agglutinating properties, as also severe physical or intellectual work. General hygienic measures and mode of life favor the acquirement of agglutinating properties, while depressing circumstances, weak heart, underfeeding and overworking act against it. A small number of tuberculous and phthisic patients were unable to tolerate the perlsucht tuberculin, the infection in their case being probably of bovine tuberculosis origin. Spengler adds, in conclusion, that he supplies his perlsucht tuberculin only to those physicians who have had special training in the specific treatment of tuberculosis. He agrees with Petruschky that the introduction of tuberculin treatment requires special training beforehand.

71. **Embryoma on Calf of Leg.**—Fischer's patient was a man of 57 who had noticed the growth of a tumor in the calf for about six years. He succumbed to the progress of miliary tuberculosis, and examination of the tumor showed it to be of congenital origin. None of the theories in vogue for the origin of congenital tumors harmonize with the findings in this case, except the Marchand-Bonnet blastomere theory, but this would explain all the findings in this typical embryoma. It contained a great variety of derivates from all the three blastodermic layers, including intestine and gland formations of all kinds. The germ remained latent for half a century before it commenced to proliferate, and it finally assumed the characteristics of a myxosarcoma. Fischer asks whether the sarcomatous degeneration could have been from an exogenous cause, or whether it was a mere coincidence that the sarcoma should happen to settle on the embryoma.

75. **Determination of Indican in Urine.**—Gürber uses osmic acid instead of calcium or ferric chlorid in the Jaffé test for indican in the urine. A reagent glass is filled one-third full of urine and the glass is then filled with a concentrated solution of hydrochloric acid, and two or three drops of a 1 per cent. solution of osmic acid are added. In a few seconds the fluid turns violet or almost pure blue, according to the proportion of indican. Osmic acid is much more reliable than the other substances previously used for the test.

76. ***Determination of Hematin in Feces.***—Siegel relates that numerous trials were made in Müller's clinic at Munich of the guaiac and benzidin tests for "occult" blood in the feces. The general conclusions are to the effect that negative findings are almost positive evidence of the absence of blood. Positive findings testify to the presence of blood if the ingestion of meat or of drugs can be excluded. The spectroscope affords the best control test.

82. **Twenty-two Years' Experience with Ovariotomy.**—Fritsch opens the stately list of articles all dedicated to Olshausen on the occasion of his seventieth birthday. The volume is a bulky one of 528 pages, with colored plates, and contains twenty-one articles. Fritsch states that he has performed ovariotomy on 1,000 patients and that 70 succumbed. The cause of death was after-hemorrhage from loosening of a ligature in 2 cases, ileus in 8, cancer in 7, contracted kidney in 2, pyelonephritis in 2, shock in the first twenty-four hours in 12, and peritonitis with purulent ovarian cysts in 6. The proportion of deaths from sepsis alone amounted to 2.33 per cent. In 48 cases the tumor was malignant.

83. **Indications and Contraindications for Drainage After Laparotomy.**—Küstner emphasizes that the indications for tamponing after a laparotomy are becoming more and more *restricted, but that in certain* cases it is still indispensable. This is especially the case when a pus pocket has to be opened secondarily, or when the intestine and bladder have been injured; also when parenchymatous hemorrhage can not be arrested by any other means, especially after detachment of adherent tumors or other lesions on the posterior sheets of the broad ligaments and peritoneum in the Douglas cul-de-sac.

84. **Indications for Myoma Operations.**—Winter's experience includes 1,000 cases of myoma in seven years. Hemorrhage occurred in about two-thirds of all his cases; it generally proceeded from submucous myomata. Pure menorrhagia was more frequent than pure metrorrhagia; the latter suggests the possibility of malignant disease or secondary degeneration of the myoma or a submucous growth. Hemorrhage in the menopause is generally due to complication with malignant disease or secondary degeneration or submucous development of the myoma. Conservative treatment is indicated in such cases only when *these three conditions* can be positively excluded. In case of pure menorrhagia, the guide to operation should be the severity of the anemia. Anemia with even 30 per cent. *hemoglobin does not contraindicate an operation.* Ergot was successful only in case of pure interstitial myomata, not larger than a child's head. Curettement of the uterus is scarcely *liable to be successful* except in case of subserous and small interstitial myomata. As the outcome is dubious, curettement should never be attempted in case of severe *anemia. Submucous myomata with hemorrhage should* be extirpated. Subserous myomata cause pain more often than other kinds except those hindered from developing freely into the abdominal cavity. Pure dysmenorrhea can be induced by a myoma alone, especially in case of submucous development. He warns that psychoses and general neuroses can not be ascribed to an accompanying myoma, and are not improved by its removal. Excessively large myomata ought to be removed, he thinks, if they interfere with the general health, even if they cause no symptoms, as also subserous tumors with a small pedicle; but otherwise not if they cause no symptoms.

85. **Ventrofixation.**—Hofmeier has examined 100 women long after he had performed ventrofixation, and is much pleased with the results of his intervention.

89. **Pyelonephritis in Pregnancy.**—Opitz has observed 84 cases of *inflammation of the renal pelvis during* pregnancy or the puerperium, and reviews the lessons learned from this experience and from the extensive literature on the subject.

90. **Affections of Female Bladder and Genitals.**—Zangemeister has tried Voelcker and Joseph's method of chromocystoscopy (described in The Journal, XLII, page 1326), and found it extremely reliable. He is surprised that gynecologists do not pay more attention to cystoscope findings. They are important in diagnosis and also as indications for operation and prognosis. He describes the behavior of the bladder in case of cervix carcinoma, *of myomata and other tumors, and* discusses further the cystocele accompanying prolapse and the conditions in case of vesicovaginal fistula.

91. **Treatment of Chronic Inflammation of the Adnexa.**—This *communication* from Olshausen's clinic does not draw a very favorable picture of the remote results of surgical intervention in the cases of chronic inflammation of the adnexa operated on there. Many of the women presented exudates, inflammatory changes in the organs left or displacement of the uterus. The immediate results are *no* criterion as to the results later. Exploratory puncture was found useful and harmless. Surgical measures should not be used until after failure of medical. Henkel considers it advisable to remove both tubes, as the chronic inflammation renders pregnancy improbable, but the physiologic function of uterus and ovaries should be respected.

93. Ventrofixation and Disturbances Later.—Seegerts discusses which methods of ventrofixation are liable to entail disturbances in childbirth or ileus, citing 40 cases from the literature. He thinks that Olshausen's technic offers the best prospects of successful outcome. He is careful to suture the uterus only at the points of insertion of the tubes. The uterus thus fastened can develop afterward normally during a pregnancy, undisturbed by the fixation at the point of attachment of the tubes. Ileus after ventrofixation is recorded in four instances. The fixation was median in each.

94. Delivery and Separation of Xiphopagus.—Jolly describes the birth of a xiphopagus and subsequent efforts to separate the living from still-born twin. The sternum and liver of each were continuous. Neither of the twins survived.

95. Spontaneous Rupture in Old Cesarean Cicatrix.—Prüsman adds another to the seven cases on record. In his case the woman had been delivered twice by Cesarean section. During the third pregnancy the integrity of the cicatrix had been determined in the course of an operation for hernia, but still it ruptured spontaneously two weeks before term. The patient was saved by prompt operation, excising the ruptured parts. The mucosa had evidently grown into the Cesarean cicatrix and undergone decidual changes, thus weakening the wall.

96. Thrombosis of Superior Mesenteric Vein.—Symptoms of ileus should suggest the possibility of thrombosis of the superior mesenteric vein when the blood has previously displayed increased coagulability by thrombosis elsewhere, or it is induced by the puerperium; also in case of congestion in the portal vein or artificial thrombus formation by operations in this region or suppurative processes. The discovery of a resistant tumor with intestinal resonance will sometimes aid in differentiation from other forms of ileus. The early appearance of ascites suggests occlusion of the vein. Amos' article is based on two cases.

97. Autointoxication After Laparotomies.—Keller relates the history of two patients who developed a febrile symptom-complex after a laparotomy in which no injury had been done to the intestines. It presented the classical picture of intoxication from intestinal putrefactions. Both patients had been constipated before the operation, and all symptoms subsided after a purgative. The case illustrates the danger from opium after a laparotomy.

98. Pathologic Desires to Urinate and Cystitis in Women.—Knorr states that one in every five of his gynecologic patients have complained of disturbances in urination, and one in every eight have exhibited chronic cystitis of the neck of the bladder. In two-thirds of all the cases with urinary disturbances, cystitis of the neck was evident. The cystitis may be attributed to infection, to venous congestion or to hyperplasia. The cystoscope is an invaluable diagnostic aid in gynecology. He describes the local findings in cystitis and also his method of local treatment, cauterizing the parts with 1 per cent. solution of silver nitrate every two or three days. An abnormally small bladder can be stretched to regain its normal capacity.

103. Catarrh of Bladder in Pulmonary Tuberculosis.—Campani has noticed symptoms of catarrh of the bladder in a number of cases of early tuberculosis. He presents arguments to prove that this catarrhal condition of the bladder is the result of the lesser acidity of the urine in the pretuberculous stage and in incipient tuberculosis. This harmonizes with the views recently advanced by some writers that hypoacidity is an accompaniment of and favors the development of tuberculosis, and accompanies it in its early stages. The hypoacidity further favors the development of pseudo-phosphaturia and cystitis, and is a depressing element for the organism in general. Alkalines should not be administered to such patients, and their diet should be regulated to prevent the possibility of "alkaline cachexia," excluding more or less the starches and vegetables.

105. Permanent Slow Pulse.—The cause of the chronic slow pulse, 30 beats to the minute, in the case described, was evidently a lesion in the central nervous system, affecting the functions of the centers that preside over the action of the heart. The patient was a man of 73, a paranoiac and paralytic for several years.

106. Serum Treatment of Pneumococcus Arthritis.—De Renzi's patient had apparently recovered from his pneumonia, but within a week of defervescence symptoms of acute articular rheumatism developed. It is the first experience of the kind in 279 cases of pneumonia in his service. He advocates in treatment of pneumonia abundance of fresh air, remarking that the mortality from pneumonia in badly ventilated rooms is enormous. He insists further on the necessity of nourishing food, giving his patients three pints of milk a day and two eggs. They escape the depression of the heart noted elsewhere, or it is very brief. He is further convinced of the necessity for alcohol in pneumonia. One of his first cases was a patient with a serious cardiac defect who had been doomed to death by other physicians, but he recovered with the use of alcohol. De Renzi gives pure alcohol, not wine, as he is thus able to measure the amount and can rely on its purity. He gives it in the formula:

℞.	Alcohol purissimo	℥ii	60
	Water	Oi	500
	Syrup of bitter orange peel	℥i	30

From 30 to 25 gm. are given during the day, with larger doses to persons accustomed to the use of alcohol. He is convinced that serum treatment is a valuable adjuvant and hopes that physicians generally will pay more attention to the serotherapy of pneumonia in future. From his experience with 28 cases treated with serum he asserts that the general health showed marked improvement; the temperature declined and resolution occurred by lysis instead of the usual crisis. The local changes did not appear to be modified by the serum, but as the general health showed such marked improvement the local manifestations seemed much less important in comparison. Besides the tonic action of the serum, it aids in raising the blood pressure. In his clinic, the blood pressure has never been low for longer than two or three days. He ascribes this to his abundant feeding and the use of alcohol, supplemented by the serum treatment.

107. **Spirochetes in Syphilis.**—Bandi found the *Spirochæta pallida* in 3 out of 5 cases of secondary syphilis in conditions that excluded the possibility of external contamination.

110. **Differentiation of Exudates and Effusions.**—Tedeschi applies the "biologic precipitation test" for the differentiation of transudates. He obtains a prepared serum from rabbits injected with egg albumin, and then has the patient eat several eggs fasting. The fluid to be examined, mixed with the prepared serum, gives the specific precipitation if it is a transudate, while there is no precipitation in case of an exudate, as a rule.

111. **Relations Between Flora and Uric Acid in Intestines.**—Carletti found that the uric acid and the bacteria in the intestines became both reduced on a milk diet and after ingestion of lemon juice, but with nothing to suggest cause and effect between the flora and the uric acid. On the other hand, when 500 gm. of calf's thymus was ingested for three days in succession, in place of other meat, no uric acid could be detected in the feces of one of the patients, while the number of bacteria increased to uncountable proportions. In the second patient the uric acid subsided to traces and the bacteria became very much more numerous, but the change was not so extreme as in the other. The conclusion seems evident that the proliferation of the bacteria on the thymus diet had some connection with the vanishing of the uric acid from the stools.

119. **Alimentary Levulosuria in Infectious Diseases.**—Rebaudi concludes from his experiences with the alimentary levulosuria test that it is the most delicate and the most reliable one at our disposal for revealing even the slightest functional disturbance in the liver cells. The degree and intensity of the disturbance can be estimated from the amount of levulose found in the urine. Intercurrent bacterial intoxication may first render manifest a latent disturbance in the liver.

123. **New Morphologic Element in Urine.**—Fittipaldi gives illustrations of what he believes to be a hitherto undifferentiated morphologic element in the urine. He calls it the "miliary tube cast," and states that it takes the eosin and other stains while the pseudo-casts of sodium oxalate, with which it might be confounded, are dissolved by acetic acid and do not take these stains. He found these new casts in certain cases of nephritis.

[illegible]. **Autogenerated Nucleoproteids in Etiology of Cirrhosis.** [illegible]tain Italian experimenters proclaim that some of the [illegible]min ingested, such as that in meat, is liable to escape the [illegible]ssimilating action of the gastrointestinal mucosa and to make its way into the circulation and to induce the formation of antibodies. Silvestri argues that if this heterogeneous albumin enters the circulation in unusual amounts, the organism is a prey to autointoxication of a much more complex nature than generally supposed. The heterogeneous albumin reaches the liver practically unmodified, with the other waste products in the blood, and in time exerts a seriously injurious action on it. The damaged liver cells in turn launch new nucleoproteids into the circulation whose effects are superadded to those of the primal cause. The future will reveal the importance of the part played by these factors in inflammation of the liver, but experimental research to date indicates that it is a very important one. The injurious action of the nucleoproteids in the circulation is similar to that of intoxication from phosphorus, alcohol and other substances which we know are capable of inducing cirrhosis. This conception explains certain cases of cirrhosis in which no etiologic factor can be discovered. If we accept the assumption of the existence of these auto-hepatolysins, we can understand that some ordinary occurrence in a predisposed individual may influence the liver to an extent that will entail true hepatitis in time. A diseased organ may be injurious to the organism not only from the lack of its normal functioning, but also because it launches into the circulation certain poisons which, besides injuring the entire economy, have a special destructive action on the organ in which they were elaborated. This conception is sustained by the beneficial results of splenectomy in certain affections, not only in Banti's disease, but in others. The improvement obtained in cirrhosis by organ treatment with liver tissue and in Banti's disease with spleen tissue, finds a plausible explanation in the hypothesis that the organ therapy, instead of merely substituting the diseased organ, is able to induce in it the production of antisubstances capable of neutralizing or precipitating the noxious substances turned out by the diseased organ or organs.

128. **Stain for Spirochetes.**—Simonelli and Bandi recommend the May Grünwald stain as far superior to others for detection of the *Spirochæta pallida*; 1 gm. of eosin and 1 gm. of methylene blue are dissolved separately in 1,000 c.c. of water each. The two solutions are then mixed and set aside for from two to seven days. The fluid is then filtered and the sediment left in the filter is rinsed again and again until the fluid comes away clear. It is then dried and dissolved in a saturated solution of pure methyl alcohol. A few drops of the stain thus made are added to the dried specimen and left in contact for from four to ten seconds. The specimen is then rinsed, dried and mounted in balsam. This stains the spirochetes while leaving the other elements in the specimen almost colorless.

129. **Protection Against Tuberculosis.**—Figari asserts his conviction that the only effectual means of protecting man against tuberculosis is by immunization carried on systematically and on a large scale.

Addresses

ARABIAN OPHTHALMOLOGY.[*]

PROF. J. HIRSCHBERG.

BERLIN, GERMANY.

I came from far abroad, following your very kind invitation, which I consider a mark of international courtesy and true fellowship. It is not my first visit to this flourishing city near the Pacific coast. The wonderful view of the rapid progress of a new culture reminds me of past cultures in the old world, and I propose to you to go back with me a thousand years and to consider the fascinating history of the old Arabian ophthalmology, which I have studied in the last five years, tracing it to its sources. I invite you to a short Arabian hour, which is as attractive as one of the "Arabian Nights;" or, if not, it does depend less on the matter than on the speaker and his want of mastering the English language.

Two questions at first must be entered on: Firstly, which were the sources at the disposal of the Arabs for the formation of their own ophthalmology? Secondly, what is the content of the Arabian work of ophthalmology? We shall learn the first in their initial, and the second in their last, text-books on opthalmology.

The classical "Memorial of Ophthalmology," composed by Ali ben Isa shortly after the year 1000 of our era, mentions as sources for his work the Greeks and his predecessor, Hunain. As we see, Arabs agree with Goethe: There are the Greeks. The Arabs erected their palace of ophthalmology principally from Greek material, but with their own additions and according to their own plan—like this wonderful mosque in Cordoba. The riches of Arabian literature are overwhelming. The text-book of Halifa, about 1260, gives in the preface a list of eighteen works on ophthalmology.

While the Greeks in the thousand years from Hippocrates to Paulos produced only five text-books of our specialty, of which not a single one was written by a specialist, not a single one has come down to us; the Arabs in the shorter flourishing time of five hundred years have created over thirty text-books on ophthalmology; the majority and the most important of them are written by specialists, and fourteen exist to-day and are collected by myself and studied by myself with the help of my learned friends.

The name of oculist among the Arabs has lost the sneer which we find so often in Galenos, but represents a title of honor. Several of these specialists control an experience, of which we can not detect any traces in the remainder of Greek literature.

The oculist bears in the Arabian the name of al-kahhal, from the word kuhl, collyre; but it signifies also the eye operator.

The first learned Arabian work on ophthalmology is composed in ten books by Hunain, an excellent Christian doctor, who lived from 808 to 873 principally in Bagdad and was acquainted with the Greek language, a great translator of Greek works on medical science. I have demonstrated that his work of the ten books on the eye is preserved for us in two medieval Latin translations, that of Demetrius, which had been taken for a work of Galenos, and that of Constantinus Africanus, who declared it his own work.

The fault of this text-book is the want of symmetry. It is welded together from ten different books on various ophthalmologic subjects, which were edited, one after the other, in the lapse of more than thirty years. The theoretical part is too long, the practical too short and torn apart. But, after all, Hunain has planned this pathway for the Arabs; the first step was the most difficult one.

Hunain's influence has lasted till the end of the Arabian era, five hundred years—a time I wish my friends who have published text-books of our science.

The more theoretical and compilatory text-books of the learned doctors, the Greek Arabs, as we may call Hunain, his nephew Hubois and the famous mathematician Tabet ben Qurra of the ninth century, were replaced, a hundred years later, by practical text-books of the oculists. The latter, meanwhile, had stored and put in order their experiences, both in hospital and in private practice.

The classical text-book of ophthalmology was for the Arabs the memorial of oculists of Ali ben Isa, the oculist, written in Bagdad, about nine hundred years ago. Last year, with my friend, Professor Lippert, I published the German edition, with commentaries. This is the oldest text-book of our specialty which we possess to-day, both complete and in the original language. As the author states that he made researches in the works of the old Greeks and made his treatise exhaustive, we may judge that we possess in this work a summary of all which had been known to the Greeks in the department of ophthalmology. But we can expect also something which surpasses the knowledge of the Greeks, because the author says that he had added something from the masters of his time and from his own experience. Beside, he has a systematic arrangement and description which is far superior to that of the Greek compilators, Aetios and Paulos.

Our Ali b. Isa gives to every important and frequent disease—as ophthalmia, trachoma, cataract—the right place and a full chapter, while he shortens less important matter. The succession of the chapters follows the anatomic order. In every chapter comes, firstly, the definition of the disease, then the objective symptoms, then the causes, finally the treatment, the general and the local. In formal respect the book is a model even for us to-day.

The famous Arabian historians, Qifti and Usaibia, tell us that the doctors and oculists work prin-

---

[*] Address by special invitation before the Section on Ophthalmology of the American Medical Association at the Portland session, July 11-14, 1905.

need to lie, but slept as he liked. Only I bandaged his eye for seven days. With this needle nobody preceded me. I have done many operations with it in Egypt.

So it is perfectly clear what Ammar intended and what he performed. He desired to get a radical operation, after which reascension was impossible—principally for such cases, in which the rest in the recumbent position, so indispensable after the common couching, by no means could be carried out. That, without the slightest doubt, is a real progress, and the first step to Daviel's extraction, the greatest progress in our branch made after the Greeks.

From the book of Ammar we learn the author's character better than from any other Arabian or even European text-book, till far into the modern times. There emerges a strong and self-confident personality. He is conscious of his own merits in the department of eye operations. With confidence he sets out to perform division of symblepharon. He has no fear of bleeding in extirpation of sarcomatous ectropion—as a result of his experience. All remedies he recommends against ophthalmia are approved in his own very long practice. Instead of many doubtful remedies he recommends a single one, which dispenses with all others. To be sure, he makes the greatest demands on the eye surgeon, that is to say, on himself; he ought to be provided with sharp senses, with sure hand, with greatest experience. He needs an experienced assistant and a full collection of well-made instruments.

Ammar is very tender for the happiness of his patients and enthusiastic for success. Shudders and desperation attack him, if the operation does not progress as he liked. If the final result is good, God was the helper and the surgeon. Warm delight fills his soul, as he could restore vision by cataract operation after three years of blindness. Full of bitter resignation he deals with the incurable cancer.

He does not quote a single author, neither Greek nor Arab. Superstitious remedies are not to be found within his book. He also is far from the use of the mud remedies, so widely used both by Greeks and by other Arabs.

Ammar made long travels and practiced and operated in various countries, in Persia, Mesopotamia, Syria, Egypt. A result of his travels is his attempt to create a cataract geography.

So through the study of Ammar's book we get a clear picture of his personality and of his work, while the former accounts gave only a few and poor remarks, not free from important errors.

From the center of the Arabian culture, the Iraq and Egypt, we go to the far east, to Persia. We found a Persian text-book of ophthalmology, never hitherto mentioned in the history of our science. The only copy is in Oxford, from where we got the photographic reproductions. The author is named Abu Ruh, known as Goldhand; the time of composition is the year 1088 of our era; the title of the book is "The Light of the Eyes."

We mention as the first important fact: no traces of old Iranian wisdom are to be found in it; the content seems to be about the same as in the Arabian text-books of that period. The second fact is the separate description of eye operations in the seventh (of the ten books) of this work. The number of eye operations is thirty, the facts and the arrangement are about the same as in the memorial of Ali b. Isa. Concerning cataract, three methods are mentioned: Couching with the needle, couching after previous opening the coats with a lancet, suction. The author declares: the hard cataract is easier for couching; the soft cataract is difficult for couching, but appropriate for suction. Excellent rules are given for after-treatment; principally the diet is very carefully controlled.

Abu Ruh, born in Gurgan, on the borders of the river Oxus, educated in the Persian language, trained by good masters both in general medicine and in the specialty, able to speak Arabian, but fond of his mother tongue, enthusiastic for his profession, but also full of ambition, a skillful surgeon, as his surname "Goldhand" proves, has composed his extensive text-book in the Persian language, overestimating his own work, underestimating that of his predecessors, more by speech, than in fact, because he likes to borrow largely from them and to apologize for it with the common literary customs. The book is full of content, put in order, clear and comprehensible, not without his own additions. The description is wordy, but plastic, because based on experience.

From the far east I beg you to accompany me to the far west of Islam, to Andalus, that means Spain. Andalus was exceedingly admired by the Europeans of the middle age because it was the only part of the world of Islam they gained acquaintance with and found it far superior to their own culture: as well as people who have seen only the Alhambra believe it to be the highest type of Islamic art. But a critical consideration of the remainders of Andalusian ophthalmology shows clearly its inferiority in comparison with the wisdom of the East.

The spirited, but rather more theoretical work of the noble Abul Mutarrif, twice minister or wezir at Sevilla, eleventh century, is entirely lost. Of Andalusian works we possess only two anonymous treatises on eye diseases, of mean value, the Latin[1] translation of Alcoati and the very long work of Gafiqi, twelfth century, entitled "The Right Guide in Ophthalmology," remarkable for its wide scope; it furnishes the science and practice of our branch within a wide compass of general knowledge of the diseases of the brain and the whole head—a specialty revived in our days and too in this country.

Each of these Andalusian works is only conserved in a single code of the Escorial, of which I got the photographic reproductions. The codes of this famous library are bound by law to their own residence.

A splendid evening glow finishes the Arabian day of creation. A short time before Arabian science and culture were kicked down by Mongolian horses, two text-books of ophthalmology appeared of such extent and such learning, that we must pass to the beginning of the nineteenth century to find their equals in Europe.

The first is "The Sufficiency in Ophthalmology," composed by Halifa of Aleppo in Syria, about 1260. Its code, which was forwarded me by the Sultan, contains five hundred sixty four pages in folio. The content of the work is very solid and valuable. It is praised by the last Arabian oculist as matchless in literature. Of course, many important passages are borrowed from the memorial of Ali b. Isa, and the character of the composition is rather scholastic. Important are the figures of eye and brain, of instruments, the table of twelve sorts of cataract. the cataract operation. Halifa was eye surgeon. He tells it himself. He had a noble practice. and sketches us a story of a lancet broken in venesection of an emir, where he advised the loadstone for extraction of the broken

The other work is "The Light of the

[1] I have discovered the fifth book of the Arabian ori

cipally and exclusively according to this book. We may call it the Arabian canon of ophthalmology. His reputation persists in the Mahometan world up to our days. We must not forget that the Islamic peoples have continued to live in middle age—they have no modern time. A Drusian oculist in Syria named Hamza, who was hanged in 1860 in Damascus, convicted of willful murder of Christians, was owner of an abstract and of a pariphrase of Ali b. Isa's memorial, the latter written in the year 1845. Owing to the great reputation of the work, we possess eight codes of it. Five of them were at my disposal. From every other Arabian text-book of ophthalmology there are only one or two codes in existence.

The work is divided into three books. The first contains the anatomy, with some remarks on physiology; the second those eye diseases which are perceptible with the senses; the third, the hidden eye diseases. About one hundred and thirty different eye diseases are described, while the Greek, Aetios and Paulos, contain only sixty, and the German Plenk, who wrote the first school book in modern times, one hundred and forty years ago, contains one hundred and twenty eye diseases.

In the work of Ali b. Isa the personality of the author does not appear in the foreground. Notwithstanding, we get the impression of a careful doctor, full of humanity and especially cautious in surgical interferences. He says: "To the cataract operation proceed with caution and circumspection." In none of the Greeks do we find any such remark. He says, also: "When the cataract needle has entered the interior of the eyeball, then address the patient with kind words to quiet his fears." No one of the Greeks has this human and useful rule, but almost all Arabs, who wrote in full on cataract operation.

How great the originality of our author has been is difficult to judge, owing to the missing links between Hunain and Ali b. Isa. But the progress from Hunain to Ali b. Isa is enormous. The book of the latter is not surpassed by anyone in the following 800 years.

Certainly in the Occident during this long time the standard of ophthalmology would have been much higher, and its use for mankind much greater if the early medieval Latin translation of the memorial were better, clearer and so more spread and propagated. But of course a text-book of ophthalmology has no use without a school, oral tradition and practical teaching. Certainly we must pass on to the beginning of the eighteenth century, when the doctrine of dioptrics accomplished by Johannes Kepler began to become more popular among the doctors, and also the strong struggle for the seat of cataract was decided against Galenos and in favor of the truth, before we find better books on our specialty than the memorial of Ali b. Isa. That is the cultural position of his work.

After the classical treatise, I come to the most original book on Arabian ophthalmology, written in Egypt by a native of Mosul about the year 1000 of our era. His name is Ammar; the title of the work "Choice of Eye Diseases." I dare say that before our translation the contents of this work were entirely unknown in the history of medicine.

Ammar was an older coeval of Ali b. Isa. He was a Mahometan, and the most clever eye surgeon of the whole Arabian literature. But he is outshined by Ali b. Isa, because his book seemed too short to the Arabs, who always insist on copiousness and completeness. He has only forty-eight eye diseases; his book contains only 1,800 lines or about 15,000 words. The only code of him is in the Escorial library in Spain. We secured its photographic reproduction and also the code of Parma itself, which contains the Hebrew translation. The so-called Latin translation of Canamusali, always spoken of in the history of our branch, was recognized by comparison to be an awkward forgery of middle age and has nothing to do with the refined work of Ammar. The most peculiar thing in Ammar's book is his six histories of cataract operation. They are clear and impressive, even to-day very attractive, without equal in the Greek literature.

Allow me, gentlemen, to give the true translation of one of these stories:

> A marvellous experience. I have operated on the eyes of a lady in a palace, in the green harem of the manor-house of Ibn al Bakri. The cataract was equally in both eyes. Three pupils who studied were present with me. I began with the right eye and operated on it and proceeded in orderly fashion and extracted the needle and bandaged the eye. Then I began the operation on the other eye. As I introduced the needle into the eyeball and was ready to couch the cataract, the lady lost consciousness and was like dead. Immediately I splashed water on her bosom, till she moved, and the spirit re-entered into her, and she became quiet. Now I had the intention to couch the cataract fo[illegible] second time. But immediately she clutched her hand, [illegible] got fits, the needle being in the interior of her eye. [illegible]ents became frightened and ran away. But I took pæonia from my pocket and gave her it to smell. Her spirit returned and she became quiet. Now I had the intention for the third time to couch the cataract and pursued the performance in a hurry and with force. Immediately her pupil dilated, the hole of the iris became as wide as if she suffered from mydriasis; notwithstanding I always held the needle in her eye with one of my hands, the other fastening the eyeball. As her condition became quiet, I finished the operation, withdrew the needle and performed the bandage. On the third day after I visited her to look the eye. Then she told me that from the hour I had left her she suffered hemiplegia. Now, of course, I was convinced that her eye was destroyed after all these accidents and loosened the knot of the bandage—full of desperation; but I found her eyes in the best condition, nearly recovered. Then I praised God the Almighty, because He is capable of all, from Him derives the love and the mercy. In all my surgery I never had a similar case.

Perhaps all the gentlemen present can say the same.

The most important thing in Ammar's work is the radical operation of the soft cataract by suction through the hollow needle constructed by himself.

The origin of this method is really dramatic—just as 730 years later the origin of Daviel's extraction. For catching the real point you must understand, that in the common couching of cataract, as performed by the Arabs after Greek model, the principal danger consisted in re-ascending of the cataract. To avoid this failure, it was considered necessary, without any exception, to lay the patient on his back for seven days after the operation. Once, at Diarbekr in the Iraq, Ammar operated on a man of 30 years for congenital cataract, which could not be couched at all, but ought to be cut into small pieces entirely and to be removed from the pupil. The man recovered fair vision, contrary to expectation. Ammar adds:

> He swore that he never rested on his back, not a single day, and he took no precautions at all. Then I constructed the hollow needle, but I did not operate with it on anybody at all, before I came to Tiberias. There came a man for operation who told me: Do as you like with me, only I can not lie on my back. Then I operated on him with the hollow needle and extracted the cataract; and he saw immediately, and did not

need to lie, but slept as he liked. Only I bandaged his eye for seven days. With this needle nobody preceded me. I have done many operations with it in Egypt.

So it is perfectly clear what Ammar intended and what he performed. He desired to get a radical operation, after which reascension was impossible—principally for such cases, in which the rest in the recumbent position, so indispensable after the common couching, by no means could be carried out. That, without the slightest doubt, is a real progress, and the first step to Daviel's extraction, the greatest progress in our branch made after the Greeks.

From the book of Ammar we learn the author's character better than from any other Arabian or even European text-book, till far into the modern times. There emerges a strong and self-confident personality. He is conscious of his own merits in the department of eye operations. With confidence he sets out to perform division of symblepharon. He has no fear of bleeding in extirpation of sarcomatous ectropion—as a result of his experience. All remedies he recommends against ophthalmia are approved in his own very long practice. Instead of many doubtful remedies he recommends a single one, which dispenses with all others. To be sure, he makes the greatest demands on the eye surgeon, that is to say, on himself; he ought to be provided with sharp senses, with sure hand, with greatest experience. He needs an experienced assistant and a full collection of well-made instruments.

Ammar is very tender for the happiness of his patients and enthusiastic for success. Shudders and desperation attack him, if the operation does not progress as he liked. If the final result is good, God was the helper and the surgeon. Warm delight fills his soul, as he could restore vision by cataract operation after three years of blindness. Full of bitter resignation he deals with the incurable cancer.

He does not quote a single author, neither Greek nor Arab. Superstitious remedies are not to be found within his book. He also is far from the use of the mud remedies, so widely used both by Greeks and by other Arabs.

Ammar made long travels and practiced and operated in various countries, in Persia, Mesopotamia, Syria, Egypt. A result of his travels is his attempt to create a cataract geography.

So through the study of Ammar's book we get a clear picture of his personality and of his work, while the former accounts gave only a few and poor remarks, not free from important errors.

From the center of the Arabian culture, the Iraq and Egypt, we go to the far east, to Persia. We found a Persian text-book of ophthalmology, never hitherto mentioned in the history of our science. The only copy is in Oxford, from where we got the photographic reproductions. The author is named Abu Ruh, known as Goldhand; the time of composition is the year 1088 of our era; the title of the book is "The Light of the Eyes."

We mention as the first important fact: no traces of old Iranian wisdom are to be found in it; the content seems to be about the same as in the Arabian text-books of that period. The second fact is the separate description of eye operations in the seventh (of the ten books) of this work. The number of eye operations is thirty, the facts and the arrangement are about the same as in the memorial of Ali b. Isa. Concerning cataract, three methods are mentioned: Couching with the needle, couching after previous opening the coats with a lancet, suction. The author declares: the hard cataract is easier for couching: the soft cataract is difficult for couching, but appropriate for suction. Excellent rules are given for after-treatment; principally the diet is very carefully controlled.

Abu Ruh, born in Gurgan, on the borders of the river Oxus, educated in the Persian language, trained by good masters both in general medicine and in the specialty, able to speak Arabian, but fond of his mother tongue, enthusiastic for his profession, but also full of ambition, a skillful surgeon, as his surname "Goldhand" proves, has composed his extensive text-book in the Persian language, overestimating his own work, underestimating that of his predecessors, more by speech, than in fact, because he likes to borrow largely from them and to apologize for it with the common literary customs. The book is full of content, put in order, clear and comprehensible, not without his own additions. The description is wordy, but plastic, because based on experience.

From the far east I beg you to accompany me to the far west of Islam, to Andalus, that means Spain. Andalus was exceedingly admired by the Europeans of the middle age because it was the only part of the world of Islam they gained acquaintance with and found it far superior to their own culture: as well as people who have seen only the Alhambra believe it to be the highest type of Islamic art. But a critical consideration of the remainders of Andalusian ophthalmology shows clearly its inferiority in comparison with the wisdom of the East.

The spirited, but rather more theoretical work of the noble Abul Mutarrif, twice minister or wezir at Sevilla, eleventh century, is entirely lost. Of Andalusian works we possess only two anonymous treatises on eye diseases, of mean value, the Latin[1] translation of Alcoati and the very long work of Gafiqi, twelfth century, entitled "The Right Guide in Ophthalmology," remarkable for its wide scope; it furnishes the science and practice of our branch within a wide compass of general knowledge of the diseases of the brain and the whole head—a specialty revived in our days and too in this country.

Each of these Andalusian works is only conserved in a single code of the Escorial, of which I got the photographic reproductions. The codes of this famous library are bound by law to their own residence.

A splendid evening glow finishes the Arabian day of creation. A short time before Arabian science and culture were kicked down by Mongolian horses, two text-books of ophthalmology appeared of such extent and such learning, that we must pass to the beginning of the nineteenth century to find their equals in Europe.

The first is "The Sufficiency in Ophthalmology," composed by Halifa of Aleppo in Syria, about 1260. Its code, which was forwarded me by the Sultan, contains five hundred sixty four pages in folio. The content of the work is very solid and valuable. It is praised by the last Arabian oculist as matchless in literature. Of course, many important passages are borrowed from the memorial of Ali b. Isa, and the character of the composition is rather scholastic. Important are the figures of eye and brain, of instruments, the table of twelve sorts of cataract, the cataract operation. Halifa was eye surgeon. He tells it himself. He had a noble practice, and sketches us a story of a lancet broken in venesection of an emir, where he advised the loadstone for extraction of the broken splinter.

The other work is "The Light of the Eyes," by

---

[1] I have discovered the fifth book of the Arabian original.

Salah ad-din, the oculist, from Hamat in Syria, about 1290. The code of Paris, of which I secured copies, contains 178 leaves in folio. The arrangement is similar to that of Ali b. Isa, but all things are more detailed and scholastically formulated, with an immense amount of quotations. Salah ad-din is a great scientist, the only Arabian oculist who dared in a treatise of ophthalmologic *practice* to explain extensively the subject of optical *theory*. That and his full chapter on cataract is reproduced in the second volume of our Arabian oculists.

It is very characteristic that the two last text-books from the fourteenth century are from Egypt, where the Mongolian hordes never had entered, and the Turks only later. These books are "The Revelation" of Sams ad-din, and "the Support" of Sadii. The last shows one mark of decadence, inasmuch as it is told therein *that the practice of suction was entirely lost in that* time and in that country, except its mention in older books and the preservation of some samples of the hollow needle. But, notwithstanding, the book is far superior to all European works on ophthalmology in the middle ages and too in the first period of modern time.

The great works of general medicine, by which the Arabs excelled, of Razi, Ibn Serafiun, Tabari, Ali b. al Abba, Ibn Sina, Abulqasim and even of Ibn Zuhr and Ibn Rusd, all of them contain a more or less full treatise of ophthalmology, which too is organically inserted, —quite different from the hand books of general medicine in our days. As a sample of this kind of literature I have edited the ophthalmology of the famous *Ibn Sina* in German translation and explanation.

I will not dwell on the monographs of various subjects of ophthalmology but will finish the explanation of Arabian literature of our specialty with the following point: In the five hundred years from 800 to 1300 of our era there were not less than sixty renowned men of the Arabian world, known to us as oculists or practitioners especially interested in our branch, authors of text-books or monographs on ophthalmology, meanwhile in medieval Europe before the twelfth century none is known as an oculist and in this century only two, one of them coming from Jerusalem, that is to say from the Arabian country, the other trained in Constantinople, this isolated remainder of Hellenistic antiquity. We are told that in Bagdad, in Cairo, in Damascus and in other cities within the reach of Arabs, there were created ocular divisions in general hospitals and even special eye clinics—*institutions not to be found in Europe before the end of the eighteenth century.*

After this summary sketch of Arabian literature on ophthalmology, I pass over to the single important chapters, in which the Arabs have produced original and special work. Of course, the Arabian anatomy of the eye is entirely derived from the Galenic, but their description is more practical. Dissection of animal eyes is referred to, but only in one author, Alcoati of Toledo.

Interesting for us are the following four points:

Firstly, the codes of Arabian text-books of our branch contain the oldest pictures of the anatomy of the eye.

Secondly, for our anatomic names of parts of the eyeball, as conjunctiva, cornea, uvea, retina, which are of daily use both in speech and writing, the lovers of these names are indebted to the translator of the Arabian works, the Mansuric book of Razi and the canon of Ibn Sina, *that is to the famous Gerard* of Cremona, who did this dull work of translating from the perfect Arabian language into the miserable Latin of middle age, not less than forty years of his life, from 1147 to 1187, in Toledo, the *former capital* of Arabian Andalus.

Thirdly, the first attempt at a comparative anatomy and physiology of the organ of vision (or a germ of it) is to be found in the *last Arabian text-book* of our branch, of Sadili. Do not forget that the extensive and classical text-books of Joseph Beer, Mackenzie and Arlt *from the first two-thirds of the last century* did not tool this brittle matter, which only in our days by the largest handbooks, as *Graefe-Saemisch*, first edition, and the French cyclopedia, is *fully dealt with*.

Fourthly, to the most important facts, which are transmitted in the anatomic part of the Manzuric book of Razi, belongs the contraction of the pupil following illumination. This fact, *that the pupil of the* healthy human eye contracts in the bright and dilates *in the dark*,—a fact, which ought to be detected by the first thinker and observer at the eye of his companion in the first evening twilight, let us say by Adam on the eyes of Eve,—strange to tell, is not to be found in any of the Greek authors, neither of a philosopher nor of a physician. But Razi has the following words: The membrane of iritis contains in its center a hole, which now dilates, now contracts, according to the quantity of light required by the crystalline: it contracts, if the illumination is bright, it dilates in the dark.

This doctrine bore good fruits for the Arabs, principally for the diagnosis of operability of cataract. Ammar has the following general rule: "Look, in the good cataract, there is contraction of pupil in the light, and dilatation of the same in the dark. This doctrine is not lost in the later text-book. In the Greek literature nothing about this valuable symptom is to be detected.

From the anatomy I pass over to the physiology and optics. Here we find a new discovery *of the highest* importance. *Ibn al-Haitam*, about the year 1000 of our era, tells us in his handbook of optics: "*All vision is performed by refraction.* Nobody of the ancients (that is of the Greeks) has told that." Of course, the full truth was not yet discovered by the Arab, he was not a Kepler; but the Greek error, *that vision is performed* by rays emanating from the eyeball, this strange theory of subjective emanation, is by the Arabs eclipsed for ever out of science.

We may dwell for a minute on the marvelous history of this author. Born in Basra from noble parents, he ascended to the dignity *of wesir in his city*. He was fond of science, a good mathematician and well versed in theoretical medicine. Once he declared that if he were in Egypt, he would so *control the Nile, that the* beneficial water supply were equal every year. Invited by the Sultan Hakim of Egypt, he came and saw at the cataracts of the Nile that *he could not stand by* his promise. He fled from the scorn of the tyrant and lived in obscurity, only devoted to science. Every year he wrote a copy of three works, of Euclid's elements, of the middle mathematicians and of the Almagest of Ptolemy and brought these codes to the market of Cairo, where immediately they were sold for 180 dinars (that is about $300), a sum sufficent for his life. Strange to say, to-day in the whole Mahometan world, from Morocco to Asia Minor and North India, not a single copy of this work could be sold, except to a European or American purchaser. So high was the Arabian standard of culture formerly; so low it is now, tramped down by the hoofs of Mongolian and Turkish horses. The great mass of the Caucasian race, even those who believe themselves to be educated, have an entirely wrong judgment, because they mingle the old Arabian with the actual Turks in Asia Minor or with the Berbers in Morocco, both of course having adopted from the Arabs the Islam.

The pathology and therapeutics of ophthalmology is elaborated by the Arabs evidently after the Greek model. But the pupils have surpassed their masters in the systematic arrangement of the matter and in accuracy.

Compare the succession of eye diseases in the compilation of Paulos or Aetios with the text-book of Ali b. Isa and others: the Arabian composition does not differ very much from that of a text-book of our days. But they described several eye diseases, unknown to the Greeks. For instance the sabal, which to-day is called pannus. They described under this name, first, the deep vascularisation of the cornea, which we observe in constitutional keratitis; secondly the superficial vascularisation, which is peculiar to the pannus trachomatosus. They sketched the thick fleshy pannus, the shortening of the conjunctival sac, the origin of pannus from trachoma. They invented the circumcision of conjunctiva for this pannus, which Furnari of Paris, in the year 1862, has introduced as his own invention under the name of tonsura conjunctivalis; but I am sure he has borrowed this method in North Africa, during his long stay, from the native practitioners. Variations on this performance have been observed in Egypt lately and imitated enthusiastically by Professor Schmidt-Rimpler.

The treatment of trachoma, so common and wearying a disease in the Orient, is based by the Arabs on excellent principles. "If the trachoma is chronic and inveterate, there is no help except friction with sugar or with the iron; but as long as it is thin and in the beginning, the cure is by application of sharp collyres." Who listens to that proposition may think that it is taken from one of our text-books; but it is nine hundred years old.

This cataract (ὑπόχυμα of the Greeks) is called by the Arabs ma,' that means water, or al-ma' an-nazil fi 'l ain, the water descending to the eye. Hence the medieval name cataract, which originally means the descending water and which is of daily use among us.

Concerning the seat of cataract, there were discussions. But we learn that the best and oldest clinicians and the oldest oculists put the cataract behind the iris; but that beginning with the year 1000, through Ibn Sina and Ali b. Isa the anterior surface of the pupil was preferred.

Have the Arabs occasionally confounded cataract with other eye diseases? Certainly. But that happened also to some of the modern oculists, even in the nineteenth century. Carron du Villards in Paris confesses that he took a fungus medullaris of the retina in its first period for cataract and that he undertook reclination.[2] I have myself observed as a traveler, twenty years after discovery of the ophthalmoscope, that a famous cataract operator selected for extraction a case of hemorrhage into the vitreous. But the saying, that the Arabs (and likewise before them the Greeks) confounded entirely cataract with hypopyon and operated on hypopyon, speaking of cataract, that is mere tale and fable, refuted and annihilated by all classical texts.

The general surgery of the Arabs is not highly esteemed. But in the special surgery of the eye they achieved great things and were far superior to the Europeans, not only of their time, but also of the following centuries.

The treasure of eye operations, inherited from the Greeks was received, cultivated and increased, principally enriched by a radical operation of cataract. In the Arabian literature for the first time we meet with oculists well educated and experienced, who without the slightest doubt had themselves performed hundreds or thousands of eye operations. We meet with eye surgeons full of boldness, self-confidence and ability, like the great Ammar; we learn the splendid results of the cataract operations, as of Ibn Raqiqa.

The excellent two tables of Halifa contain the figures of not less than thirty-six instruments for eye surgery; that is enough, compared with the last and very complete work on eye surgery, composed in our days by Prof. Czermak and containing seventy-six such figures.

Concerning cataract operation I would like to particularize, if I had the hope of keeping your attention or the courage of taking more of your time, on which I have trespassed so long; so I refer to the remarks I mentioned about this operation and conclude with the statement, that the Arabian literature has also created a kind of oculistic ethics. The system of medical ethics of the Arabs goes back to that of the Greeks and has its roots in the oath of Hippocrates. This old and venerable scripture was translated very early into Arabic by Hunain, the author of the first Arabian ophthalmology. In his life he himself found occasion to refer to that oath. The Caliph Mutawakkil desired to try Hunain and asked from him a mortal poison. Between treasures amassed and torments piled the doctor denied the poison to the tyrant, because it was forbidden, he said, firstly by his religion and secondly by his doctor's oath.

It is very interesting that the Arabian oculists arranged this oath of Hippocrates for their text-books and that they added to the old and general command, not to administer a mortal poison, the new and specialistic match, nor a salve or ointment which destroys vision.

We come to the end. The judgment of August Hirsch, that the Arabs have not contributed to the real progress of ophthalmology, is entirely wrong. He had not studied a single one of all these Arabian text-books. And also, the history of a speciality must be written by a specialist, versed in the matter of the speciality and of the historical sources. I acknowledge that the proficiencies of Arabian ophthalmology in comparison with their large literature are not so very great, but they are remarkable and should not be denied. Besides, during this total darkness in the medieval Europe they lighted and fed the lamps of our science—from the Guadalquivir to the Nile and to the river Oxus. Thirdly they were the only masters of medieval Europe in our branch. So we must state that the name of the Arabs, which is written with indelible characters on the firmament, never will be effaced from the memorial stones of ophthalmologic art and science.

---

[2] "Glioma of the Retina Simulating Hypopyon" is the title of a paper which appeared in the Ophthalmic Review, January, 1903.

Medical Societies.—With proper effort and affiliation of the profession throughout the country there would be practically established in every town a postgraduate medical school. The standing of the profession as such would be raised and a better feeling of fellowship would prevail. With such a united effort those disposed to be treacherous and unprofessional would find it unprofitable and soon fall in line. Young men, old men, all should join hands; there is no excuse for not doing so.—*Kansas City Medical Index-Lancet.*

IMPORTANT SUBJECTS WHICH HAVE OCCUPIED THE ATTENTION OF GYNECOLOGISTS AND OBSTETRICIANS DURING THE PAST YEAR.

CHAIRMAN'S ADDRESS BEFORE THE SECTION ON OBSTETRICS AND DISEASES OF WOMEN, AT THE FIFTY-SIXTH ANNUAL SESSION OF THE AMERICAN MEDICAL ASSOCIATION, PORTLAND, ORE., JULY 11-14, 1905.

C. L. BONIFIELD, M.D.
CINCINNATI, OHIO.

The rules of the Association demand that the chairman address the Section for a few minutes on the welfare of the Section and on the recent progress in gynecology and obstetrics. I am very willing to perform the first part of this task, for my experience as secretary has given me, some decided opinions on how its usefulness can be maintained and increased.

In the first place, the office of secretary should be a comparatively permanent one. The same man should be re-elected not less than four times.

In order that a suitable man be induced to hold this office for five years, his duties should be made as light as possible. Members should assist him by furnishing titles and abstracts promptly when asked for. Papers should be ready for publication when read. Failure to observe this rule causes a vast amount of unnecessary labor and annoyance.

The secretary should be relieved of the necessity of disposing of the bound volume of the transactions, and the trustees should allow him a sufficient salary to pay his traveling expenses and a stenographer.

In the second place, the number of papers to be read should be limited to thirty, and the time limit of fifteen minutes should be strictly enforced in the reading of them. Longer papers may be prepared for publication and read in abstract. For the most part, papers should be read by men of more than local reputation. A moment's thought will convince any one that this is for the greatest good of the greatest number. The attendance almost invariably swells as the time approaches for some celebrity to read and rapidly shrinks when an unknown reader takes the floor. Our system of organization may be likened to the public school system. The county society is the ward school, the state society the high school, and the American Medical Association the university. One can not expect honors in the university until he has worked in the lower grades.

Papers should be read in the order in which they appear on the program. The secretary groups them as best he can; the chairman approves of the arrangement; members of the Association come from other sections at a given hour to hear a paper on some special subject in which they are interested, and are greatly disappointed to find some one else reading on an entirely different subject. Members should not ask for the privilege of reading their papers out of order for trivial reasons.

There has been some discussion as to the scope to which papers in this Section should be limited, some claiming that it should follow the lines adopted by the American Gynecological Society and the American Association of Obstetricians and Gynecologists and deal with all surgical conditions arising between the perineum and the diaphragm, inclusive, while others claim that its work should be limited to obstetrics and pure gynecology, leaving the surgical affections of the appendix, stomach, liver and kidneys to the Section on Surgery and Anatomy. To my mind, there are two serious objections to this last arrangement: First, it is in the problems of surgery in the upper abdominal region that many of the men who belong to this Section are at the present time most interested, and on which they prepare their best papers, and if they can not read them here they will go elsewhere. Second, the surgical section can not give all the good men who wish to read papers on these subjects an opportunity to do so.

It seems to me the best arrangements that could be made would be to change the name of this Section to "Section on Obstetrics, Diseases of Women, and Abdominal Surgery." Ten papers could be allotted to each branch. Papers on kindred subjects would be so grouped on the program as to attract to a session those most competent to discuss the subjects under consideration.

GYNECOLOGY.

Let us now glance at some of the subjects that have most attracted the attention of gynecologists and obstetricians since last we met. Neither science is now making the rapid strides forward that gynecology was making a decade ago. Recent progress has mainly consisted in appraising at their true value procedures previously introduced to the profession.

One of the subjects most discussed during the year is the treatment of retrodisplacements of the uterus. The fact that so many methods are advised is proof positive that no ideal method, which is applicable to all cases, has yet been found. Probably this is expecting too much. Retrodisplacements may be divided broadly into two classes: those requiring treatment and those not requiring it. The majority of the latter class the gynecologist does not see; the condition producing no symptoms, he is not consulted. When symptoms are produced some kind of treatment is required. The only question is whether it shall be by surgical operation or by other methods. In my opinion, many patients are subjected to operation in whom just as good and possibly better results could be obtained by careful, painstaking nonoperative treatment. The fact that the uterus is displaced if the malposition be not congenital, or the result of inflammation of the appendages, shows that there is a disproportion between the weight of the uterus and the strength of its supports. To effect a cure this proportion must be restored. The weight of the uterus must be reduced or the supports must be strengthened. As a matter of fact, both are usually attempted. When the condition is treated non-surgically, the weight of the uterus is reduced by hot douches, tampons, rest in bed, free purgation, and by temporarily holding it in approximately its normal position. The supports are strengthened by rest, tonics and suitable exercise.

In surgical treatment the weight of the uterus is reduced by curettage, trachelorrhaphy or amputation of the cervix. The supports are strengthened by adding to their number (ventrosuspension), changing their direction so that they act at greater mechanical advantage (Gilliam's operation), or by restoring the function of some of the supports by taking up the slack in them (shortening the round or sacrouterine ligaments). In what cases can we hope for success without surgery?

The uterus must be free from adhesions and capable of being readily replaced. The appendages must be healthy and also free from adhesions, the posterior cul-de-sac must be fairly deep and the perineum intact so that tampons and pessaries can be used successfully for temporary support. The patient must be willing to submit to treatment for an indefinite length of time and to remain where the gynecologist can see her as often as necessary. Prolapse of an ovary is not a contraindication for this treatment if the ovary goes up into position with the uterus when the latter is replaced. In some more complicated cases, non-operative treatment may be successful, in the cases described it will be, if skillfully and persistently used.

When it comes to surgical treatment, the wealth of operations advised may be confusing, but one of three will usually answer very well (not including curettage, trachelorrhaphy and perineorrhaphy, which, of course are done along with the one selected if indicated). Alexander's operation does as well as any in the cases which I have described, as those in which a cure can be accomplished without surgery, and if the gynecologist decides to operate in such cases it is the operation to use, on account of its simplicity and freedom from danger.

When there are complications, it is necessary to open the peritoneal cavity to deal with them. A free incision in the median line of the abdomen gives the best opportunity for doing everything that may be necessary; this often includes removal of the appendix. The uterus is freed from adhesions and the tubes and ovaries dealt with as they may require. If their complete removal is necessary or if the woman is past the menopause, ventrosuspension is indicated. This operation should not be done, when any other will answer in child-bearing women, and some method of shortening the round ligaments usually will answer.

I formerly folded the ligaments, covered as they are with peritoneum, on themselves once or twice, employing catgut for sutures. Some of my patients relapsed after six months or a year. I reopened the abdomen and found nothing but peritoneal adhesions to show for my former operation. Now, therefore, I strip the ligaments of peritoneum, fold them once, stitch the folds together with chromicized catgut, push the folded portion through the slit in the peritoneum and stitch it to the ligaments again toward its distal end, then close the peritoneum.

I have been loth to trust shortening of the sacrouterine ligaments alone, because these are little more than folds of peritoneum, and I should expect them to give away again in time.

Cancer of the uterus is another subject that forces itself on the attention of the gynecologist. I hope before this Section meets many more times we will know something of the cause and prevention of this horrible disease and that its treatment will have lapsed into comparative unimportance; at the present time, however, nothing can overshadow this phase of the subject. There are some who think with Baldy that all efforts at radical cure are worse than futile, and others who believe that every case seen early should be subjected to the Rumpf-Reis-Clark operation.

Every few months I meet on the streets a healthy woman whose uterus I removed nearly ten years ago for cancer of the inside of the cervix. This one case, if there were no others, would encourage me to continue to operate for cancer of the uterus.

Just how radical the operation is to be in a given case must depend on the general as well as the local condition of the patient, and the surgeon's skill and speed as an operator.

His best judgment must be used to make the operation not too severe for the patient before him. No matter how thoroughly we may be convinced by deductive reasoning that the most radical procedures are the proper ones, we must not forget that Byrne, Baker and Reamy years ago obtained results by the high amputation of the cervix that have not been improved on by the ever-advancing radicalism of the present time.

It has seemed to me that the cautery may have played an important rôle in the results of these early operators, and for several years, therefore, I have begun the operation in every case of cancer of cervix in which I had hopes of giving permanent relief by destroying the growth with the cautery, and proceeding with an abdominal hysterectomy at once. I have not usually removed retroperitoneal glands, because prolonging the operation in this way seems to add too much to the primary mortality. Great care is always taken to trim away a considerable collar from the upper end of the vagina after the uterus is removed, because cancer of the cervix is prone to recur in the vaginal scar. To do anything less radical than this I regard as doing a palliative operation for relief of symptoms only.

In his presidential address before the American Gynecological Society, Dr. E. C. Dudley proposed an operation for the relief of incontinence of urine, which I believe will prove to be one of the real advances made by gynecology this year.

OBSTETRICS.

The toxemia of pregnancy has attracted the attention of a good many writers on obstetrics during the year. The prevalent belief is that this toxemia may be caused by the derangement of function of the kidneys, liver or thyroid gland. In fatal cases, the pathologic changes have been most frequently found in the liver. This being true, and veratrum viride being one of the most active stimulants of the liver known, besides being a spinal depressant, and so many severe cases having been reported in which this drug has been used successfully, it is difficult to understand why any case should be allowed to terminate fatally without giving this powerful but most tractable drug a trial.

Vaginal Cesarean section has become a well-recognized surgical procedure in cases suitable for its employment. It is always to be remembered that the child must be delivered through the bony pelvis after the cervix has been incised, so the wise operator will assure himself that this is possible before selecting this operation as the proper one.

Cesarean section or the Porro operation is no doubt indicated in certain cases of placenta prævia, but the indications should be those existing in the patient, not in the operator. The fact that the operator is more familiar with surgical than with obstetric procedures, is not a valid indication when skilled obstetricians are within call.

At the St. Paul meeting, our late lamented colleague, Dr. George J. Englemann, read a paper on "The Increasing Sterility of American Women," and during the past year the subject has attracted a good deal of attention from the lay press. It is one of the very greatest importance to the nation, and I know of no work this Section could do that would redound more to its credit than to make some collective investigations that would determine whether the decrease is real or apparent and if real the causes therefor. It would probably be found that it is real; that intentional limitation of the size of the family after marriage is the greatest cause; that late marriages is next in importance; that the higher education of women is a cause only in so much as it delays marriage and renders a woman averse to the cares of maternity.

Back of all these causes would be found the fact that Americans have drifted away from the "simple life." The luxuries of a few decades ago are the necessities of to-day. The struggle for respectable existence becomes more and more intense, and intelligent and educated people hesitate to start in the race of life, children who will be handicapped by poverty.

TUBERCULOSIS OF THE KIDNEY.*

J. G. SHERRILL, A.M., M.D.
LOUISVILLE, KY.

This is a subject worthy of more consideration than has generally been accorded to it, and the condition is *one which is likely to be overlooked for long periods* when great benefit could result from proper treatment. As several patients have come under my care during the past eighteen months, my attention has been called more directly to the subject.

It has been claimed that renal tuberculosis occurs in 2 per cent. of all patients suffering from this disease, and, while many of these cases are inoperable, there still remains a considerable number in which no other lesion can be located save that in one kidney. Kroenlein[1] uses the terms "solitary" and "combined" tuberculosis of the kidney instead of "primary" and "secondary," and it would seem well to follow his classification, for such distinction will prove of value in the management of a given case. In his 34 cases of nephrectomy only 12 were of the solitary form, and it is reasonable to suppose, he says, that other latent foci have been present, though not detected.

The essential cause, the *Bacillus tuberculosis,* gaining entrance into the circulation through the respiratory or alimentary tracts, with or without the involvement of a lymph gland, is transported to the kidney by the blood, and, becoming localized there, may cause a renal tuberculosis. That the kidney escapes the disease in many cases is well established by Kahlden and others, while the lower urinary tract becomes involved from the presence of bacteria in the urine. In addition to infection from this source, there is undoubted evidence of the disease ascending from the bladder prostate or testis. Again, the possibility of infection of the kidney in the course of a Pott's disease by contiguity must not be overlooked. Morris[2] mentions a case of secondary renal infection from a tuberculous empyema which had perforated the diaphragm. An intestinal or peritoneal tuberculosis might excite disease of the kidney by contact. Such external infection must be rare, as pointed out by Tilden Brown.[3] Hunner[4] gives the proportion of circulatory infection as much larger than the ascending contamination from the bladder. He says: "With the widest margin in favor of primary bladder infection I have classed but 5 of the 35 cases under this heading." Israel gives the proportion as 8 in 30 cases. Hunner[4] points out the probability that ascending infection is more frequent in males. Steinthal (quoted by Bab[5]) has carefully examined 24 cases with reference to this point and states that the bacilli reach the pyramids through the blood stream and there begin their activity. Thence they proceed toward the papilla and finally break into the calices and the pelvis of the kidney, and are carried down by the trickling urine, thus causing disease of the urinary passages. Steinthal states that the fact is often overlooked that renal and testicular tuberculosis may co-exist independently of each other, and that the process in the former is descending while the latter is ascending, and mentions three cases observed by Israel in which the kidney and testicle were simultaneously involved, while the bladder remained perfectly healthy. He also says that it is difficult to explain how the disease situated in the bladder, testicle and prostate proceeds upward, except it be that the disease is so extensive that it extends from cell to cell, and tissue to tissue, or that the ureter possesses a certain amount of "anti-peristaltic" property, a view held by Posner.

If the extension is upward we would expect a continuity of diseased tissue in the first instance, and in the case of reversed peristalsis we would look for some obstruction below to produce such action. In proof of the latter factor being of importance, mention can be made of the experiments of Baumgarten and Albarran. The former failed to produce renal tuberculosis by infecting the prostate and seminal vesicles, while the latter obtained tuberculosis of the kidney by inoculating the ureter and applying a ligature distal to the infection. That obstructions to the urinary passages of man are of importance in causing renal infections no one will deny. The discussion on this point has been carried on for a long time, but the weight of evidence presented seems to justify the conclusion that the majority of cases of tuberculosis of the kidney and ureter result from circulatory infection, that some occur from ascending disease, and that in some instances the kidney and the genital organs are simultaneously attacked. It is an undoubted fact that many conditions favor the growth of the bacteria after they are localized in any part of the economy, and without such predisposing factors tuberculosis would become a very rare disease. The same conditions which favor the development of tuberculosis in any part of the body are equally active here: Traumatism, exposure, infectious diseases, renal stone, floating kidney, and interference with the urinary outflow are all predisposing causes. Gonorrhea, by favoring bladder and genital tuberculosis, is perhaps of importance. That the normal bladder is quite resistant to this disease is shown by the long time which often elapses before it becomes involved after the kidney is attacked.

AGE, SEX AND RACE.

Any age is susceptible to this form of the disease. Morris[2] says that the miliary type is seen most often in the young. Winternitz[6] records a case in a child of 18 months, while Tilden Brown's autopsy records from the Presbyterian Hospital, 1893 to 1896, show the extremes of age to be 2½ months and 64 years. Hunner[4] gives the greatest proportions between 20 and 30 years. In this *he agrees with Kroenlein,*[1] who comments on the frequency of its occurrence in the flowery period of life. Kroenlein reports 51 cases; 7 occurred between 17 and 20 years; 23 (45 per cent.) between 21 and 30 years; 14 between 31 and 40 years; 6 between 41 and 50 years, and 1 between 51 and 60 years.

Statistics given by different authors do not agree as to the sex most frequently affected. English writers give men as most often attacked, while Continental observers state that women are most subject to this form of the disease. In Kroenlein's[1] recent report, 38 of 51 cases were females. This discrepancy is probably due to the fact that the writers are giving individual experience and their work is largely confined to one sex.

Hunner[4] states in this connection that all of his 35 cases were in white women, although one-fifth of the patients treated in Johns Hopkins Hospital are colored.

LESIONS.

Both kidneys are affected in two-thirds of the cases when a general tuberculosis coexists, while when the lesion is limited to the kidneys, in the majority of instances, it is unilateral. Israel gives 90 per cent. of cases as unilateral, while Hunner estimates that 92 per cent. of cases in his series were unilateral at period four and a half years after the symptoms began. Kroenlein's cases coming to operation show the right kidney affected 24 times, the left 23 times, and both 4 times. These statements certainly show these patients to be favorable ones for early operation.

The kidney, in the majority of cases, is affected prior to the involvement of the bladder, although the latter organ and the ureter may be expected sooner or later to become involved. Morris[2] claims that it is not difficult generally to tell the mode of infection when examining a tuberculous kidney after its removal. He says:

> When by the blood miliary tubercles are found in the cortical substance the caseous nodules are older and wider about the bases of the pyramids than at the apices, and if they are broken down and have opened into the calices, the open vomicæ are small, even though the parenchyma be entirely destroyed. Moreover, there may be little or no extension of the diseased process into the renal pelvis or ureter. When the disease is of the ascending type the ureter and renal pelvis are indurated, thickened and perhaps ulcerated, with a quantity of cheesy material in their walls or in their lumen. The calices share in these changes, the connective tissue and urinary tubes become invaded from below upward, the vessels become obliterated, minute hemorrhages occur into the tissue, and the breaking down process spreads along the pyramids from apices to bases until large vomicæ are formed in the kidney, which communicate with the renal pelvis by large openings.

PATHOLOGY.

In circulatory infection the bacilli are localized in the neighborhood of the blood vessels, especially in the Malpighian tufts, and there produce the characteristic cell proliferation of tuberculosis. Morris states that the dead bacilli, as well as living organisms, may be the cause of the early cell division. This can only be true to a slight degree, and we may safely claim that all progressive lesions have resulted from the presence of the living organisms. Any dead bacteria present, with good reason, can be considered as dying after their implantation.

The lesion in the kidney may be single or multiple. Tubercle, as seen here, differs in nothing from that tissue wherever found in the body. As these nonvascular nodules increase in size, coagulation necrosis and caseation occur. The process of caseation may progress until the entire secreting structure of the kidney becomes caseous. The process is essentially a slow one and may continue for years before the destruction of the kidney tissue is complete. The presence of a mixed infection is likely to render the tissue destruction more rapid. The *Bacillus coli communis* and the *Streptococcus pyogenes* are the bacteria most frequently present, but in the larger number of cases cultures are free of mixed infection (Hunner). Localized portions of kidney structure may be destroyed or the entire organ may become a cheesy, suppurating mass. The capsule of the organ, naturally resistant, becomes thickened and forms, as it were, the capsule of a cheesy cyst.

Sooner or later, the diseased process extends to the calices, and points of ulceration are seen communicating with the renal pelvis. These openings are minute at first, but soon increase in size. When the ulcerative process destroys a blood vessel, hemorrhage occurs into the renal pelvis and may be observed macroscopically in the urine. Early hemorrhage may result from the congestion produced by the infection, the overdistended vessels permitting the escape of the blood cells into the urinary stream. As the disease progresses, more and more vessels are obliterated until finally very little blood reaches the kidney and the hemorrhage becomes diminished in amount. This seems to agree with Casper's[7] statement that hemorrhage occurs in the first stage of the disease and becomes rarer as the disease progresses.

The flow of bacilli-laden urine through the kidney pelvis and ureter excites a congestion, then an inflammation, and finally a tuberculosis of these structures. The ureter becomes thickened and indurated and finally ulcerated. Microscopic section of its wall may show true tubercular tissue. The bladder apparently resists the infection for long periods of time in many cases, perhaps because of the free escape of urine when it reaches this organ, or on account of the natural resistance of its mucous membrane. It would seem probable that the frequent micturition noted early in this disease is a conservatism on the part of the organism to protect the bladder from the infectious urine. The bladder will show early in the affection, perhaps, nothing more than the pouting of a congested ureteral orifice. There soon follows this a congestion of the bladder on the side of the diseased gland where it is most exposed to the urine from the affected ureter. Still later the entire bladder is inflamed and finally tuberculous deposits and spots of ulceration appear. The other ureter may become inflamed and an ascending infection reach the other kidney which may have escaped up to this time, although such result is not met very frequently.

The ascending form is certainly less frequent than the one just described, and especially so in the female. From a deposit in the epididymis, vas, seminal vesicles, prostate or bladder, the process slowly extends by continuity of tissue to the ureter and finally to the kidney. In this type of the infection, we find the kidney most affected on the side of the greatest amount of bladder inflammation. Ascent of the infection would be facilitated by any obstruction to the urinary outflow, as a stricture of the urethra, an enlarged prostate or a phimosis.

In women, pelvic growths or a pregnant uterus in like manner can aid in the production of an ascending disease. Obstruction to the urinary passages will also favor a descending tuberculosis by retaining in the kidney bacilli that might otherwise escape harmlessly with free urinary flow. Miliary tuberculosis of the kidney is seen in children who are the subjects of acute miliary tuberculosis. The kidney, usually on each side of the body, is studded with these minute gray tubercles. The infection comes from the circulation and spreads in the same way. The progress of the disease, however, is very rapid, and, according to Morris,[2] it gives no symptoms directly indicative of the renal lesion and does not come within the scope of surgical treatment.

---

[7] Casper: "Nierentuberkulose." Deutsche Klinik, Berlin und Vienna, 1904, iv, 3, pp.173-216.

In some cases a form of sclerosis is excited, which is thought by Morris to be due to impaired virulence of the bacteria. The experiments of L. Bernard and M. Salomon[8] show caseating forms resulting from the injection of an ethereal extract of tubercle bacilli, while a chloroform extract gives rise to a sclerotic form.

Hydronephrosis may result from thickening and infiltration of the ureter, and is most likely to follow an ascending infection. Klippel reports a case in which the whole kidney was a polycystic mass and a tuberculous cystic degeneration existed without there being any obstruction of the ureter (Morris). I have seen one case resembling this, and consider the condition as by no means rare. The presence of a mixed infection may result in the destruction of the bacilli and in the formation of an abscess; thus in some instances recovery may occur. In other cases, the abscess invades surrounding structures and there plants a tuberculous process which progresses to a fatal termination. As a result of such rupture on the surface, a sinus may persist for years, or by invading a hollow viscus a fistula may be formed. Such a condition existed in one of my cases, the communication having been established with the posterior wall of the right colon. This case was considered unique until an investigation of the subject showed that several similar cases were on record. Lazarus Riverius and Fernelius[9] have recorded cases of gastrorenal fistula. Morris says that there is some uncertainty in the diagnosis of these cases, but mentions one case, verified by postmortem, in which a fistula from the kidney communicated with the left end of the greater curvature of the stomach. Cases of openings into the duodenum, colon and other portions of the intestine, as well as into the lungs, are on record.

Any of the adjacent structures may become tuberculous as the result of an extension from the kidney, although the resistance of the capsule is likely to prevent such occurrence unless the ureter is obstructed, thus causing tension within the renal capsule.

SYMPTOMS.

The onset of the disease is very insidious in the majority of cases, an exception being the sudden onset of pain in a previously healthy patient, probably due to the obstruction of the rigid ureter by clots of blood or by cheesy material. There is pain in the back, varying from a slight soreness to a severe backache, sometimes radiating down the side to the bladder and not much influenced by motion. Bazy[10] gives three points at which pain may be elicited on pressure: 1. At a point level with the umbilicus and about three fingers' breadth away, para-umbilical or superior ureteral pain; 2, below the costal border, right or left, subcostal; 3, above at the summit of the costomusclar angle, the lumbar. All are usually present, the para-umbilical most often. Painful and frequent urination is often the cause of the complaint, even, as Hunner says, in the absence of bladder involvement. Sometimes the vesical irritation is very distressing. An increased amount of urine may be passed early in the disease, with a diminished quantity later. Morris claims that polyuria (thamuria of Tilden Brown), in a frail patient of tuberculous family, for which no other cause is assignable, should excite suspicion of renal tuberculosis.

Pyuria is present in every case; at least dead cells can be found which are identical with pus cells. Hematuria is often one of the early symptoms of the disease, and in most cases blood can be found at some time in the urine. The blood is usually equally diffused throughout the urine, which is acid in reaction except when cystitis coexists, but at times the hemorrhage is severe and persistent. Cases are recorded in which clots have almost filled the bladder. Albumin is always present when the infundibulum and ureter are involved. Casts are not of necessity present, but were noted in 10 per cent. of the cases in Hunner's report.

The size of the kidney varies, sometimes being normal and again being greatly increased in size. The presence of perirenal inflammation is likely to give the impression of a tumor.

The presence of tubercle bacilli in the urine is an important, but not positive sign of renal disease, as Kahlden has shown their presence in the urine without pathologic change in the urinary tract. Bacilli, with blood and pus in the urine, in the absence of a diseased bladder or prostate, would seem to be pathognomonic. On the other hand, the absence of the organisms in the urine is not a proof that the kidney is sound. Hunner advises repeated daily examinations for bacteria rather than a number of examinations on the same day, and claims that the differential stain should always be used. Tubercle bacilli were found in 15 of 22 of his cases in which a note was made. Casper[6] found them in 80 per cent. of his cases and confirmed the nature of the germ by cultures and, with more extended time, by inoculation of guinea-pigs. Kroenlein[1] found bacilli in 17 of 31 cases. Tilden Brown[3] claims that cultures should be made from the urine separated by ureteral catheter, and also that inoculations are of great value.

Morris does not attach much importance to the tuberculin test, while Hunner considers it of value in cases free of fever. Casper[7] and Schmidt[11] use the tuberculin reaction. This test seems to me to be of value only to establish the fact that the patient has a tuberculous lesion, the location of the focus to be determined by other means.

The general symptoms are those of tuberculosis anywhere—evening rise of temperature, loss of flesh, anorexia, pallor of the skin, night sweats and, perhaps, edema of the feet. Later, hectic symptoms may be present. I have been surprised to note how well preserved my patients have been, and am led to believe that too much stress has been laid on wasting of flesh as a symptom.

DIAGNOSIS.

The diagnosis is to be made by the history, general appearance of the patient, pain less severe than that of stone, and coming on slowly as a rule, dysuria, polyuria,

hematuria, pyuria in acid urine and the presence of albumin. The demonstration of the bacilli, with the other symptoms mentioned, will be conclusive.

Morris claims that the early diagnosis of renal tuberculosis may save the patient the necessity of a subsequent partial or complete nephrectomy by placing him in a suitable climate and under proper dietetic and hygienic surroundings. While the opinion of this authority carries great weight both on account of his large experience and because of his careful observation of these cases, it must be confessed that the results of such treatment are so uncertain that we are more inclined to operation when we make an early diagnosis of unilateral disease. We are willing to admit that some of these patients live for years, and complete recovery has been known to occur. In any event, an early diagnosis at once gives the attendant an intelligent and clear conception of the case, and he can then judge which is the best plan to follow. The very difficulty of diagnosis should stimulate one to the most careful study of cases presenting symptoms which point to tuberculosis of the kidney. The following are the conditions most likely to be mistaken for this disease, viz.: Renal calculus, pyelonephrosis, renal new growths, tuberculosis of the bladder, cystitis.

Morris states that in the early stages it is difficult, if not impossible, in the absence of the bacilli of tuberculosis, to diagnose tuberculous kidney from renal calculus. He says that the chief reliance should be placed on the constitutional signs of tuberculosis. We are often called on to make a diagnosis before any constitutional evidences of the disease are apparent, and without the history of tuberculosis in the family. The personal history of the patient is of the greatest value in arriving at a correct diagnosis. He will state that for some time he has suffered with a dull pain in one or both loins, with an occasional attack in which the suffering is more acute; that he has had frequent urination and has passed a thick, ropy urine of pale color, or at times it has contained blood. Following the attacks of pain, he may have passed plugs of mucopus or blood clots, but no gravel. On the other hand, a patient suffering from calculus will give a history of passing urine which is high colored and concentrated, causing smarting on micturition. He may have suffered several attacks of renal colic, with the severe pain and profuse sweating incident to this condition, following which small, gritty particles may have been found in the urine. Fever is more likely to be observed in renal tuberculosis than in stone. Hematuria is nearly always present in tuberculous kidney, although it may be so slight that only microscopic examination will detect it, while in stone the hemorrhage is often intermittent and follows an attack of colic. Movement of the patient is more likely to excite both hemorrhage and pain in cases of stone than in renal tuberculosis. Pyuria is constant in tuberculosis unless the ureter is blocked, and it is sometimes intermittent in stone. Casts may be found in each and can not be considered diagnostic. In stone, crystals are usually found in the urine; they are rarely present in tuberculosis of the kidney. The demonstration of the bacilli of tuberculosis in the urine in connection with the symptoms mentioned will make the diagnosis positive, provided disease of the bladder and prostate is excluded. Careful cystoscopy and ureteral catheterization will exclude all possible error.

The question of the advisability of catheterizing the ureter in these cases is one worthy of some consideration. There can be no doubt of its value in making a positive conclusion, but some objections can be offered to catheterization of a healthy ureter in the presence of disease of the other kidney or of the bladder, owing to the danger of infecting the healthy side. That such infection is possible we do not deny, but that it occurs with any degree of frequency we are inclined to doubt. As stated before, the experiments of Albarran seem to show that disease of the ureter only follows infection when an obstruction exists below. Hunner, in speaking of Case 2 of his series, says he thinks it fair to question whether the infection was not carried up to the left ureter by the catheter eight years previously. There is certainly no sufficient proof in support of his conclusion and it would seem more reasonable to attribute the infection to the same source as the one which caused the disease of the right kidney. Hunner claims that by the use of Kelly's speculum with an oblique end sufficient urine may be collected for examination by simply holding it under the ureteral orifice when the patient is in the knee-chest position. In the female, this may be a satisfactory measure, but it will prove more difficult than catheterization in the male and permits of the possibility of error. Albarran advises the use of a catheter in the diseased ureter as large as it will hold, thus obstructing it, and the collection of the urine from the other kidney from the bladder. When the bladder is not extensively diseased, I believe that catheterization of the ureter is justifiable and a means of diagnosis without equal. Moreover, by its use the activity and usefulness of the other kidney can be determined more satisfactorily than by any other means.

From pyelonephrosis the diagnosis is made by its slow course, the absence of high fever, and the evidence of acute sepsis seen in the latter condition, and by the presence of tubercle bacilli. While the urine may be acid in pyelonephrosis, it is usually alkaline, as it is most often a sequel of cystitis.

Tuberculosis of the kidney differs from renal tumors by a much less abundant hematuria, its persistent pyuria, its history, the presence of fever, the presence of other tuberculous lesions, if any, and by the demonstration of the organisms in the urine.

Bladder tuberculosis will not give rise to the lumbar pain or tenderness, and the blood will not be mixed equally through the urine, which will probably give an alkaline reaction. Successful ureteral catheterization will show the absence of bacilli in the urine coming from the kidneys, which would be good presumptive evidence of the absence of renal disease.

In cystitis, the history is quite different from tuberculosis except in the frequency of micturition. The presence of a large amount of pus in an alkaline urine, with great vesical tenesmus and pain, with, perhaps, the history of a local infection, and the absence of lumbar pain or polyuria and of bacilli, will be sufficient for a diagnosis.

When the diagnosis of renal tuberculosis is made, then is to be determined which kidney is affected and the condition of the other organ, both as to disease and efficiency. The gland affected can be determined in some instances from the history of pain, but this has in many reported cases been misleading, especially when both kidneys are involved and an attack is to be made on the one in which the disease has progressed the farthest. The most satisfactory method of meeting all these indications is by ureteral catheterization. The urine segregated in this way will show the presence or absence of bacilli, their abundance if present in each, and by cryoscopy and the urea tests the ability of either gland ney bacilli that might otherwise escape harmlessly with free urinary flow. Miliary tuberculosis of the kidney is seen in children who are the subjects of acute miliary tuberculosis. The kidney, usually on each side of the body, is studded with these minute gray tubercles. The infection comes from the circulation and spreads in the same way. The progress of the disease, however, is very rapid, and, according to Morris,[2] it gives no symptoms directly indicative of the renal lesion and does not come within the scope of surgical treatment.

In some cases a form of sclerosis is excited, which is thought by Morris to be due to impaired virulence of the bacteria. The experiments of L. Bernard and M. Salomon[8] show caseating forms resulting from the injection of an ethereal extract of tubercle bacilli, while a chloroform extract gives rise to a sclerotic form.

Hydronephrosis may result from thickening and infiltration of the ureter, and is most likely to follow an ascending infection. Klippel reports a case in which the whole kidney was a polycystic mass and a tuberculous cystic degeneration existed without there being any obstruction of the ureter (Morris). I have seen one case resembling this, and consider the condition as by no means rare. The presence of a mixed infection may result in the destruction of the bacilli and in the formation of an abscess; thus in some instances recovery may occur. In other cases, the abscess invades surrounding structures and there plants a tuberculous process which progresses to a fatal termination. As a result of such rupture on the surface, a sinus may persist for years, or by invading a hollow viscus a fistula may be formed. Such a condition existed in one of my cases, the communication having been established with the posterior wall of the right colon. This case was considered unique until an investigation of the subject showed that several similar cases were on record. Lazarus Riverius and Fernelius[9] have recorded cases of gastrorenal fistula. Morris says that there is some uncertainty in the diagnosis of these cases, but mentions one case, verified by postmortem, in which a fistula from the kidney communicated with the left end of the greater curvature of the stomach. Cases of openings into the duodenum, colon and other portions of the intestine, as well as into the lungs, are on record.

Any of the adjacent structures may become tuberculous as the result of an extension from the kidney, although the resistance of the capsule is likely to prevent such occurrence unless the ureter is obstructed, thus causing tension within the renal capsule.

SYMPTOMS.

The onset of the disease is very insidious in the majority of cases, an exception being the sudden onset of pain in a previously healthy patient, probably due to the obstruction of the rigid ureter by clots of blood or by cheesy material. There is pain in the back, varying from a slight soreness to a severe backache, sometimes radiating down the side to the bladder and not much influenced by motion. Bazy[10] gives three points at which pain may be elicited on pressure: 1. At a point level with the umbilicus and about three fingers' breadth away, para-umbilical or superior ureteral pain; 2, below the costal border, right or left, subcostal; 3, above at the summit of the costomusclar angle, the lumbar. All are usually present, the para-umbilical most often. Painful and frequent urination is often the cause of the complaint, even, as Hunner says, in the absence of bladder involvement. Sometimes the vesical irritation is very distressing. An increased amount of urine may be passed early in the disease, with a diminished quantity later. Morris claims that polyuria (thamuria of Tilden Brown), in a frail patient of tuberculous family, for which no other cause is assignable, should excite suspicion of renal tuberculosis.

Pyuria is present in every case; at least dead cells can be found which are identical with pus cells. Hematuria is often one of the early symptoms of the disease, and in most cases blood can be found at some time in the urine. The blood is usually equally diffused throughout the urine, which is acid in reaction except when cystitis coexists, but at times the hemorrhage is severe and persistent. Cases are recorded in which clots have almost filled the bladder. Albumin is always present when the infundibulum and ureter are involved. Casts are not of necessity present, but were noted in 10 per cent. of the cases in Hunner's report.

The size of the kidney varies, sometimes being normal and again being greatly increased in size. The presence of perirenal inflammation is likely to give the impression of a tumor.

The presence of tubercle bacilli in the urine is an important, but not positive sign of renal disease, as Kahlden has shown their presence in the urine without pathologic change in the urinary tract. Bacilli, with blood and pus in the urine, in the absence of a diseased bladder or prostate, would seem to be pathognomonic. On the other hand, the absence of the organisms in the urine is not a proof that the kidney is sound. Hunner advises repeated daily examinations for bacteria rather than a number of examinations on the same day, and claims that the differential stain should always be used. Tubercle bacilli were found in 15 of 22 of his cases in which a note was made. Casper[6] found them in 80 per cent. of his cases and confirmed the nature of the germ by cultures and, with more extended time, by inoculation of guinea-pigs. Kroenlein[1] found bacilli in 17 of 31 cases. Tilden Brown[3] claims that cultures should be made from the urine separated by ureteral catheter, and also that inoculations are of great value.

Morris does not attach much importance to the tuberculin test, while Hunner considers it of value in cases free of fever. Casper[7] and Schmidt[11] use the tuberculin reaction. This test seems to me to be of value only to establish the fact that the patient has a tuberculous lesion, the location of the focus to be determined by other means.

The general symptoms are those of tuberculosis anywhere—evening rise of temperature, loss of flesh, anorexia, pallor of the skin, night sweats and, perhaps, edema of the feet. Later, hectic symptoms may be present. I have been surprised to note how well preserved my patients have been, and am led to believe that too much stress has been laid on wasting of flesh as a symptom.

DIAGNOSIS.

The diagnosis is to be made by the history, general appearance of the patient, pain less severe than that of stone, and coming on slowly as a rule, dysuria, polyuria, hematuria, pyuria in acid urine and the presence of albumin. The demonstration of the bacilli, with the other symptoms mentioned, will be conclusive.

Morris claims that the early diagnosis of renal tuberculosis may save the patient the necessity of a subsequent partial or complete nephrectomy by placing him in a suitable climate and under proper dietetic and hygienic surroundings. While the opinion of this authority carries great weight both on account of his large experience and because of his careful observation of these cases, it must be confessed that the results of such treatment are so uncertain that we are more inclined to operation when we make an early diagnosis of unilateral disease. We are willing to admit that some of these patients live for years, and complete recovery has been known to occur. In any event, an early diagnosis at once gives the attendant an intelligent and clear conception of the case, and he can then judge which is the best plan to follow. The very difficulty of diagnosis should stimulate one to the most careful study of cases presenting symptoms which point to tuberculosis of the kidney. The following are the conditions most likely to be mistaken for this disease, viz.: Renal calculus, pyelonephrosis, renal new growths, tuberculosis of the bladder, cystitis.

Morris states that in the early stages it is difficult, if not impossible, in the absence of the bacilli of tuberculosis, to diagnose tuberculous kidney from renal calculus. He says that the chief reliance should be placed on the constitutional signs of tuberculosis. We are often called on to make a diagnosis before any constitutional evidences of the disease are apparent, and without the history of tuberculosis in the family. The personal history of the patient is of the greatest value in arriving at a correct diagnosis. He will state that for some time he has suffered with a dull pain in one or both loins, with an occasional attack in which the suffering is more acute; that he has had frequent urination and has passed a thick, ropy urine of pale color, or at times it has contained blood. Following the attacks of pain, he may have passed plugs of mucopus or blood clots, but no gravel. On the other hand, a patient suffering from calculus will give a history of passing urine which is high colored and concentrated, causing smarting on micturition. He may have suffered several attacks of renal colic, with the severe pain and profuse sweating incident to this condition, following which small, gritty particles may have been found in the urine. Fever is more likely to be observed in renal tuberculosis than in stone. Hematuria is nearly always present in tuberculous kidney, although it may be so slight that only microscopic examination will detect it, while in stone the hemorrhage is often intermittent and follows an attack of colic. Movement of the patient is more likely to excite both hemorrhage and pain in cases of stone than in renal tuberculosis. Pyuria is constant in tuberculosis unless the ureter is blocked, and it is sometimes intermittent in stone. Casts may be found in each and can not be considered diagnostic. In stone, crystals are usually found in the urine; they are rarely present in tuberculosis of the kidney. The demonstration of the bacilli of tuberculosis in the urine in connection with the symptoms mentioned will make the diagnosis positive, provided disease of the bladder and prostate is excluded. Careful cystoscopy and ureteral catheterization will exclude all possible error.

The question of the advisability of catheterizing the ureter in these cases is one worthy of some consideration. There can be no doubt of its value in making a positive conclusion, but some objections can be offered to catheterization of a healthy ureter in the presence of disease of the other kidney or of the bladder, owing to the danger of infecting the healthy side. That such infection is possible we do not deny, but that it occurs with any degree of frequency we are inclined to doubt. As stated before, the experiments of Albarran seem to show that disease of the ureter only follows infection when an obstruction exists below. Hunner, in speaking of Case 2 of his series, says he thinks it fair to question whether the infection was not carried up to the left ureter by the catheter eight years previously. There is certainly no sufficient proof in support of his conclusion and it would seem more reasonable to attribute the infection to the same source as the one which caused the disease of the right kidney. Hunner claims that by the use of Kelly's speculum with an oblique end sufficient urine may be collected for examination by simply holding it under the ureteral orifice when the patient is in the knee-chest position. In the female, this may be a satisfactory measure, but it will prove more difficult than catheterization in the male and permits of the possibility of error. Albarran advises the use of a catheter in the diseased ureter as large as it will hold, thus obstructing it, and the collection of the urine from the other kidney from the bladder. When the bladder is not extensively diseased, I believe that catheterization of the ureter is justifiable and a means of diagnosis without equal. Moreover, by its use the activity and usefulness of the other kidney can be determined more satisfactorily than by any other means.

From pyelonephrosis the diagnosis is made by its slow course, the absence of high fever, and the evidenee of acute sepsis seen in the latter condition, and by the presence of tubercle bacilli. While the urine may be acid in pyelonephrosis, it is usually alkaline, as it is most often a sequel of cystitis.

Tuberculosis of the kidney differs from renal tumors by a much less abundant hematuria, its persistent pyuria, its history, the presence of fever, the presence of other tuberculous lesions, if any, and by the demonstration of the organisms in the urine.

Bladder tuberculosis will not give rise to the lumbar pain or tenderness, and the blood will not be mixed equally through the urine, which will probably give an alkaline reaction. Successful ureteral catheterization will show the absence of bacilli in the urine coming from the kidneys, which would be good presumptive evidence of the absence of renal disease.

In cystitis, the history is quite different from tuberculosis except in the frequency of micturition. The presence of a large amount of pus in an alkaline urine, with great vesical tenesmus and pain, with, perhaps, the history of a local infection, and the absence of lumbar pain or polyuria and of bacilli, will be sufficient for a diagnosis.

When the diagnosis of renal tuberculosis is made, then is to be determined which kidney is affected and the condition of the other organ, both as to disease and efficiency. The gland affected can be determined in some instances from the history of pain, but this has in many reported cases been misleading, especially when both kidneys are involved and an attack is to be made on the one in which the disease has progressed the farthest. The most satisfactory method of meeting all these indications is by ureteral catheterization. The urine segregated in this way will show the presence or absence of bacilli, their abundance if present in each, and by cryoscopy and the urea tests the ability of either gland to carry on the urinary function can be determined. Wright and Kilmer[12] have proposed a new method of determining the secretory efficiency of the kidney based on the point at which the urine, or blood from which that urine was obtained, will allow complete hemolysis of a standard suspension of red blood corpuscles. They claim by their method to be able to estimate a patient's ability to undergo a surgical operation. Those desiring further study of the method are referred to the original monograph.

PROGNOSIS.

Usually the prognosis is quite unfavorable, except in circumscribed disease of one kidney which is recognized early and treated surgically. The gravity is increased when both kidneys are involved and when it occurs in the course of a general tuberculosis, also when the ureter and bladder are extensively affected and when other tuberculous foci are present in the body. While usually progressing to an unfavorable termination, the course is often very slow and years may elapse before the fatal issue. Recovery without operation is possible, but of infrequent occurrence. E. J. Ill[13] reports several cases of apparent recovery, and Morris says "certain well-marked cases of renal tuberculosis have been temporarily or permanently benefited, and some actually cured, by a change of residence and suitable climate, under a proper hygienic and dietetic régime." Cases are recorded where a patient lived for some years with a diseased kidney after one had been removed. In the absence of disease in other organs, the prognosis is much improved by the early partial or complete removal of a single diseased kidney.

The mortality of nephrectomy was given by Gross in 1885 as 40 per cent., by Vigneron in 1893 as 29.8 per cent. operative mortality and 38.40 per cent. general mortality. Israel placed it at 18 per cent. in 1896, and Tilden Brown[3] in 1898 at 7 per cent. Kroenlein[1] records 34 nephrectomies with 10 deaths and 24 recoveries. Two patients died in the first days after operation, two within two months, two within three months, one in four and one in nine months, and one each in seven and eleven years. His operative mortality was 5.88 per cent. and the general mortality 29.40 per cent.

The number of permanent cures is greater after complete nephrectomy, or nephroureterectomy, than after nephrotomy, or any other plan of treatment. Still, in some cases, nephrotomy or partial nephrectomy would seem to be indicated. Morris reports seven cases of partial nephrectomy, in three of which the patients were later subjected to total removal of the organ, while four were known to be well at considerable periods after operation. He also mentions a case in which one kidney had been previously removed, in which he made a partial one-third resection of the remaining kidney, and the patient was alive four years after the last operation.

He records four nephroureterectomies with three recoveries and one death from hemoptysis and pulmonary tuberculosis five weeks later. Hunner reports thirteen such (complete and partial) operations done by Dr. Howard Kelly and his associates without mortality, a very favorable result.

The duration of the disease before the case comes to operation is not readily determined. Kroenlein[1] says in this connection that one-half of his patients had urinary disturbances for a year; the others dated back two, three, four or more years. One patient gave a positive history on this point, having been seized with sudden, severe pain in the lumbar region after lifting, and was bedridden for seven weeks until he came to operation. In my opinion, when the attention of the profession has been called to this condition, the diagnosis will be made earlier and the mortality will be materially reduced by a prompt and radical attack on the disease.

TREATMENT.

Physicians are firmly convinced that this is essentially a surgical disease when it is recognized while it is solitary and when only one kidney is affected; also that by conservative operation much benefit may result even in the later stages of the affection. In cases in which operation is not accepted, or in which it is deemed unwise, much good may result from the use of such measures as are employed in the treatment of tuberculosis in other parts of the organism, viz., good food, fresh air, suitable climate, creosote, cod liver oil, and some of the various tissue builders. Especially important is the use of warm clothing and the protection of the surface from cold. In addition to these measures, the removal of the primary focus of infection is advisable when feasible.

In the light of recorded literature on this subject, it must be concluded that an early and complete nephrectomy, or nephroureterectomy, will offer most for these sufferers. Kelly has demonstrated also the feasibility of a partial extirpation of the bladder at the same sitting, when a portion of that organ is diseased. This is the ideal procedure for such condition, yet there are so many recorded cases in which the bladder involvement has been relieved after nephrectomy or nephroureterectomy that we are justified in leaving the bladder for a time to see if the symptoms will not subside. The results obtained by Morris in seven cases of partial nephrectomy are sufficient to justify a resort to that operation in well-selected cases. It would appear especially useful when both kidneys are involved, the second being subjected to operation after the wound in the first has healed. Albarran has recommended that incision of the kidney be made prior to its removal, first surrounding it with gauze sponges to protect the adjacent structures. This appears to be a very rational procedure and conducive to the best conservatism.

Nephrotomy is only indicated where the loss of the gland would probably result fatally; it is useful when both kidneys are diseased and when fever is present or when considerable tissue destruction has taken place. The results of this operation have not been flattering, perhaps, in part, because it has been employed late in the affection.

Following any of these operations considerable attention should be paid to the functional activity of the remaining kidney, and the skin called to its assistance during convalescence, by the use of heat to the surface, diaphoretic drugs, and the administration of large quantities of water. After recovery from the operation the same hygienic measures advised for non-operative cases are to be employed.

It is unnecessary to mention the technic of operations on the kidney, except to emphasize some points which are worthy of consideration. The most important of these is the protection of the surrounding tissues from infection, whether the attack is made through the loin or through the abdomen. In some cases of perinephritic infection, protection is impossible, but the convalescence will be short or protracted, according to the successful avoidance of contamination from the diseased kidney. Kelly has graphically described the operation of nephroureterectomy, and his technic may well be followed. The suggestion that the upper end of the ureter, left after nephrectomy, be cauterized and inverted is offered as a safeguard. In order to prevent an excessive amount of infectious material passing into the bladder during the manipulation of the kidney before removal, a ligature should be placed around the ureter near the kidney pelvis, or a clamp may be similarly placed. Even with this precaution the bladder will contain considerable necrotic tissue, and it should be thoroughly washed before the patient leaves the table. The bladder should receive careful attention for some time and such treatment as its condition demands.

DISCUSSION.

Dr. O. C. Smith, Hartford, Conn., said that it seems to him that because the tubercle bacillus is such an illusive body, it should not be dismissed without extraordinary search. When it has been found, although it may not be pathognomonic, it is the most distinctive symptom. There may be pyuria, hematuria and other symptoms and still not tuberculosis of the kidney. One can not devote too much time in a search for this bacillus. A twenty-four-hour specimen of urine should be collected, and thorough and repeated search made. If not found, the specimen should be centrifugalized and a guinea-pig inoculated. In this way the diagnosis may be brought out. Cryoscopy is a decided aid in these cases, and Kümmel claims that since employing it he has not had a kidney death, i. e., not a death from anuria of the remaining kidney. The procedure requires time and practice. One who is actively engaged in surgical work can not devote the necessary time to cryoscopy and skiagraphy. Dr. Smith has recently advocated before the state society the importance of some one being skilled and equipped in this line of work in ever community. In skiagraphic work physicians in Hartford have been somewhat limited, and have not been able to do the work so successfully as those in larger cities, but lately, with improved apparatus, their results have been more satisfactory. Just before Dr. Smith left for the session a calculus was detected in the kidney of a young woman who had suffered for twelve years. Following the advice given in an article by Dr. Lewis Gregory Cole of New York—who made a positive diagnosis in 167 patients, all of whom were operated on, revealing but two errors in diagnosis—the patient was placed on the back with the tube over the abdomen, and the picture taken very quickly, the patient holding her breath so as to limit the excursions of the diaphragm. If any movement is made the shadow will be enlarged. Operation proved the diagnosis to be correct, a stone the size of a marble being removed from the kidney pelvis.

Dr. M. H. Richardson, Boston, said that the first question of practical importance is whether or not both kidneys are affected; a second and still more important one, whether, in case of a proposed operation on one kidney there is another kidney, and if there is another, whether it is capable of adequate elimination. It would be absurd to operate on one kidney if the other one was incapable of doing the work of two. It seems to Dr. Richardson that the treatment of tuberculosis of the kidney, which is not an uncommon disease, is clear if it is certain that one kidney alone is affected. If a focus exists in one kidney only, that kidney should be extirpated; it is only in this way that the disease can be cured. Even after the removal of a tubercular kidney the chances of a permanent cure are not worth much, because of the probable incompleteness of even so extensive an operation as nephrectomy; this has been his experience. When there are sinuses dependent on a tubercular focus the prognosis is also unfavorable. The best treatment is the complete removal of the kidney in the very beginning of the tubercular process rather than when ureter, bladder and the other kidney and ureter have had time to become infected. Dr. Richardson has become convinced that in tuberculosis, as in malignant disease, the best treatment is thorough extirpation at the earliest possible moment. Palliative measures should be resorted to in tuberculosis only when surgical treatment is impracticable.

Dr. Thomas W. Huntington, San Francisco, declared that the opinion of any individual in the face of voluminous evidence gleaned from the experience of frequent operators, must be taken with some allowance. While he is aware that there is excellent authority for partial operations on the kidney under certain circumstances, his experience accords closely with that of Dr. Richardson. Dr. Huntington has found that extirpation of one kidney at almost any stage in the progress of tubercular disease has given results altogether satisfactory, and he recalled three such patients who are now living valuable lives and so far as he can tell, are absolutely healthy. In the first there was a kidney as large as a fetal head, which was converted into a pus sac. It could not be removed through the ordinary incision without first exhausting its contents. The man at the end of four years shows a gain of nearly thirty pounds and is able to follow his ordinary occupation. In the second case there was a persistent sinus due to ureteral involvement for eighteen months. There was ultimate closure of the sinus and return to health. He does not acknowledge that he has been crippled in the least by the operation. The third case was analogous to the previous ones, and the patient is living after five years perfectly well. In two of the cases tubercle bacilli were clearly demonstrated. In the third no research was made. While a wise conservatism should prevail in our estimate of the value of partial operations, nevertheless it is possible that physicians shall grow more optimistic in that regard in the future in dealing with tuberculous disease of the kidney in its early stages.

Dr. Casper W. Sharples, Seattle, Wash., said that hemorrhage of the kidney is often the first symptom and may be very trifling in quantity and amount. The first and only symptom sometimes is the small quantity of blood, although some bladder irritation may be present. When these conditions are present it is a pretty good indication that we should be on the lookout for tuberculous kidney. The hemorrhage may occur with or without irritation of the bladder, but is usually accompanied by painful urination. He mentioned a case in which he operated for tuberculous kidney and in which operation was followed by a profuse hemorrhage eighteen hours later. The blood seemed to come from the stomach. Physical examination of the lungs showed no tubercular deposits in the chest and the sputum showed nothing; the patient simply vomited a large quantity of blood and died.

Dr. T. W. Nuzum, Brodhead, Wis., said that he saw Dr. Mayo do an operation recently in which, after removing the kidney, he injected into the ureter twenty drops of 95 per cent. carbolic acid, after which he tied it. Dr. Mayo said that very little would reach the bladder and that it would be harmless. This impressed Dr. Nuzum as being of importance in obviating the necessity of removing the ureter.

Dr. Jacob Frank, Chicago, said that there are certain symptoms which are referred entirely to the bladder and not to the kidney at all, and that this is of importance in the diagnosis. He has had two such cases in which the bladder was apparently normal; cystoscopic examination showed it to be normal except for the presence of pus. It has been said that the ureter is generally enlarged in the ascending type, but his observation has been that it is also enlarged in the descending. Dr. Frank thinks that as a general rule when the kidney is enlarged and the physician knows that there is an infection present, and when the adhesions are extensive and there is danger of opening into the peritoneal cavity, nephrectomy should be done in two sittings. When a patient has recovered from the first operation then only is a complete nephrectomy indicated. In one case he was unfortunate enough to open the pleura and the patient died. Postmortem examination showed that the tuberculosis was no doubt caused by stones which were in both kidneys, and whether the patient died from the opening of the pleura or from the failure of the other kidney to do the work of both kidneys, he does not know. If he had another case in which the kidney was enlarged and the adhesions strong, he would prefer to do the operation in two parts. He operated sixteen years ago on a woman with tuberculosis of the kidney who is still alive. Her bladder symptoms have remained, but they are not so severe as they were when she had her tubercular kidney.

to carry on the urinary function can be determined. Wright and Kilmer[12] have proposed a new method of determining the secretory efficiency of the kidney based on the point at which the urine, or blood from which that urine was obtained, will allow complete hemolysis of a standard suspension of red blood corpuscles. They claim by their method to be able to estimate a patient's ability to undergo a surgical operation. Those desiring further study of the method are referred to the original monograph.

PROGNOSIS.

Usually the prognosis is quite unfavorable, except in circumscribed disease of one kidney which is recognized early and treated surgically. The gravity is increased when both kidneys are involved and when it occurs in the course of a general tuberculosis, also when the ureter and bladder are extensively affected and when other tuberculous foci are present in the body. While usually progressing to an unfavorable termination, the course is often very slow and years may elapse before the fatal issue. Recovery without operation is possible, but of infrequent occurrence. E. J. Ill[13] reports several cases of apparent recovery, and Morris says "certain well-marked cases of renal tuberculosis have been temporarily or permanently benefited, and some actually cured, by a change of residence and suitable climate, under a proper hygienic and dietetic régime." Cases are recorded where a patient lived for some years with a diseased kidney after one had been removed. In the absence of disease in other organs, the prognosis is much improved by the early partial or complete removal of a single diseased kidney.

The mortality of nephrectomy was given by Gross in 1885 as 40 per cent., by Vigneron in 1893 as 29.8 per cent. operative mortality and 38.40 per cent. general mortality. Israel placed it at 18 per cent. in 1896, and Tilden Brown[3] in 1898 at 7 per cent. Kroenlein[1] records 34 nephrectomies with 10 deaths and 24 recoveries. Two patients died in the first days after operation, two within two months, two within three months, one in four and one in nine months, and one each in seven and eleven years. His operative mortality was 5.88 per cent. and the general mortality 29.40 per cent.

The number of permanent cures is greater after complete nephrectomy, or nephroureterectomy, than after nephrotomy, or any other plan of treatment. Still, in some cases, nephrotomy or partial nephrectomy would seem to be indicated. Morris reports seven cases of partial nephrectomy, in three of which the patients were later subjected to total removal of the organ, while four were known to be well at considerable periods after operation. He also mentions a case in which one kidney had been previously removed, in which he made a partial one-third resection of the remaining kidney, and the patient was alive four years after the last operation.

He records four nephroureterectomies with three recoveries and one death from hemoptysis and pulmonary tuberculosis five weeks later. Hunner reports thirteen such (complete and partial) operations done by Dr. Howard Kelly and his associates without mortality, a very favorable result.

The duration of the disease before the case comes to operation is not readily determined. Kroenlein[1] says in this connection that one-half of his patients had urinary disturbances for a year; the others dated back two, three, four or more years. One patient gave a positive history on this point, having been seized with sudden, severe pain in the lumbar region after lifting, and was bedridden for seven weeks until he came to operation. In my opinion, when the attention of the profession has been called to this condition, the diagnosis will be made earlier and the mortality will be materially reduced by a prompt and radical attack on the disease.

TREATMENT.

Physicians are firmly convinced that this is essentially a surgical disease when it is recognized while it is solitary and when only one kidney is affected; also that by conservative operation much benefit may result even in the later stages of the affection. In cases in which operation is not accepted, or in which it is deemed unwise, much good may result from the use of such measures as are employed in the treatment of tuberculosis in other parts of the organism, viz., good food, fresh air, suitable climate, creosote, cod liver oil, and some of the various tissue builders. Especially important is the use of warm clothing and the protection of the surface from cold. In addition to these measures, the removal of the primary focus of infection is advisable when feasible.

In the light of recorded literature on this subject, it must be concluded that an early and complete nephrectomy, or nephroureterectomy, will offer most for these sufferers. Kelly has demonstrated also the feasibility of a partial extirpation of the bladder at the same sitting, when a portion of that organ is diseased. This is the ideal procedure for such condition, yet there are so many recorded cases in which the bladder involvement has been relieved after nephrectomy or nephroureterectomy that we are justified in leaving the bladder for a time to see if the symptoms will not subside. The results obtained by Morris in seven cases of partial nephrectomy are sufficient to justify a resort to that operation in well-selected cases. It would appear especially useful when both kidneys are involved, the second being subjected to operation after the wound in the first has healed. Albarran has recommended that incision of the kidney be made prior to its removal, first surrounding it with gauze sponges to protect the adjacent structures. This appears to be a very rational procedure and conducive to the best conservatism.

Nephrotomy is only indicated where the loss of the gland would probably result fatally; it is useful when both kidneys are diseased and when fever is present or when considerable tissue destruction has taken place. The results of this operation have not been flattering, perhaps, in part, because it has been employed late in the affection.

Following any of these operations considerable attention should be paid to the functional activity of the remaining kidney, and the skin called to its assistance during convalescence, by the use of heat to the surface, diaphoretic drugs, and the administration of large quantities of water. After recovery from the operation the same hygienic measures advised for non-operative cases are to be employed.

It is unnecessary to mention the technic of operations on the kidney, except to emphasize some points which are worthy of consideration. The most important of these is the protection of the surrounding tissues from infection, whether the attack is made through the loin or through the abdomen. In some cases of perinephritic infection, protection is impossible, but the convalescence will be short or protracted, according to the successful avoidance of contamination from the diseased kidney. Kelly has graphically described the operation of nephroureterectomy, and his technic may well be followed. The suggestion that the upper end of the ureter, left after nephrectomy, be cauterized and inverted is offered as a safeguard. In order to prevent an excessive amount of infectious material passing into the bladder during the manipulation of the kidney before removal, a ligature should be placed around the ureter near the kidney pelvis, or a clamp may be similarly placed. Even with this precaution the bladder will contain considerable necrotic tissue, and it should be thoroughly washed before the patient leaves the table. The bladder should receive careful attention for some time and such treatment as its condition demands.

DISCUSSION.

Dr. O. C. Smith, Hartford, Conn., said that it seems to him that because the tubercle bacillus is such an illusive body, it should not be dismissed without extraordinary search. When it has been found, although it may not be pathognomonic, it is the most distinctive symptom. There may be pyuria, hematuria and other symptoms and still not tuberculosis of the kidney. One can not devote too much time in a search for this bacillus. A twenty-four-hour specimen of urine should be collected, and thorough and repeated search made. If not found, the specimen should be centrifugalized and a guinea-pig inoculated. In this way the diagnosis may be brought out. Cryoscopy is a decided aid in these cases, and Kümmel claims that since employing it he has not had a kidney death, i. e., not a death from anuria of the remaining kidney. The procedure requires time and practice. One who is actively engaged in surgical work can not devote the necessary time to cryoscopy and skiagraphy. Dr. Smith has recently advocated before the state society the importance of some one being skilled and equipped in this line of work in ever community. In skiagraphic work physicians in Hartford have been somewhat limited, and have not been able to do the work so successfully as those in larger cities, but lately, with improved apparatus, their results have been more satisfactory. Just before Dr. Smith left for the session a calculus was detected in the kidney of a young woman who had suffered for twelve years. Following the advice given in an article by Dr. Lewis Gregory Cole of New York—who made a positive diagnosis in 167 patients, all of whom were operated on, revealing but two errors in diagnosis—the patient was placed on the back with the tube over the abdomen, and the picture taken very quickly, the patient holding her breath so as to limit the excursions of the diaphragm. If any movement is made the shadow will be enlarged. Operation proved the diagnosis to be correct, a stone the size of a marble being removed from the kidney pelvis.

Dr. M. H. Richardson, Boston, said that the first question of practical importance is whether or not both kidneys are affected; a second and still more important one, whether, in case of a proposed operation on one kidney there is another kidney, and if there is another, whether it is capable of adequate elimination. It would be absurd to operate on one kidney if the other one was incapable of doing the work of two. It seems to Dr. Richardson that the treatment of tuberculosis of the kidney, which is not an uncommon disease, is clear if it is certain that one kidney alone is affected. If a focus exists in one kidney only, that kidney should be extirpated; it is only in this way that the disease can be cured. Even after the removal of a tubercular kidney the chances of a permanent cure are not worth much, because of the probable incompleteness of even so extensive an operation as nephrectomy; this has been his experience. When there are sinuses dependent on a tubercular focus the prognosis is also unfavorable. The best treatment is the complete removal of the kidney in the very beginning of the tubercular process rather than when ureter, bladder and the other kidney and ureter have had time to become infected. Dr. Richardson has become convinced that in tuberculosis, as in malignant disease, the best treatment is thorough extirpation at the earliest possible moment. Palliative measures should be resorted to in tuberculosis only when surgical treatment is impracticable.

Dr. Thomas W. Huntington, San Francisco, declared that the opinion of any individual in the face of voluminous evidence gleaned from the experience of frequent operators, must be taken with some allowance. While he is aware that there is excellent authority for partial operations on the kidney under certain circumstances, his experience accords closely with that of Dr. Richardson. Dr. Huntington has found that extirpation of one kidney at almost any stage in the progress of tubercular disease has given results altogether satisfactory, and he recalled three such patients who are now living valuable lives and so far as he can tell, are absolutely healthy. In the first there was a kidney as large as a fetal head, which was converted into a pus sac. It could not be removed through the ordinary incision without first exhausting its contents. The man at the end of four years shows a gain of nearly thirty pounds and is able to follow his ordinary occupation. In the second case there was a persistent sinus due to ureteral involvement for eighteen months. There was ultimate closure of the sinus and return to health. He does not acknowledge that he has been crippled in the least by the operation. The third case was analogous to the previous ones, and the patient is living after five years perfectly well. In two of the cases tubercle bacilli were clearly demonstrated. In the third no research was made. While a wise conservatism should prevail in our estimate of the value of partial operations, nevertheless it is possible that physicians shall grow more optimistic in that regard in the future in dealing with tuberculous disease of the kidney in its early stages.

Dr. Casper W. Sharples, Seattle, Wash., said that hemorrhage of the kidney is often the first symptom and may be very trifling in quantity and amount. The first and only symptom sometimes is the small quantity of blood, although some bladder irritation may be present. When these conditions are present it is a pretty good indication that we should be on the lookout for tuberculous kidney. The hemorrhage may occur with or without irritation of the bladder, but is usually accompanied by painful urination. He mentioned a case in which he operated for tuberculous kidney and in which operation was followed by a profuse hemorrhage eighteen hours later. The blood seemed to come from the stomach. Physical examination of the lungs showed no tubercular deposits in the chest and the sputum showed nothing; the patient simply vomited a large quantity of blood and died.

Dr. T. W. Nuzum, Brodhead, Wis., said that he saw Dr. Mayo do an operation recently in which, after removing the kidney, he injected into the ureter twenty drops of 95 per cent. carbolic acid, after which he tied it. Dr. Mayo said that very little would reach the bladder and that it would be harmless. This impressed Dr. Nuzum as being of importance in obviating the necessity of removing the ureter.

Dr. Jacob Frank, Chicago, said that there are certain symptoms which are referred entirely to the bladder and not to the kidney at all, and that this is of importance in the diagnosis. He has had two such cases in which the bladder was apparently normal; cystoscopic examination showed it to be normal except for the presence of pus. It has been said that the ureter is generally enlarged in the ascending type, but his observation has been that it is also enlarged in the descending. Dr. Frank thinks that as a general rule when the kidney is enlarged and the physician knows that there is an infection present, and when the adhesions are extensive and there is danger of opening into the peritoneal cavity, nephrectomy should be done in two sittings. When a patient has recovered from the first operation then only is a complete nephrectomy indicated. In one case he was unfortunate enough to open the pleura and the patient died. Postmortem examination showed that the tuberculosis was no doubt caused by stones which were in both kidneys, and whether the patient died from the opening of the pleura or from the failure of the other kidney to do the work of both kidneys, he does not know. If he had another case in which the kidney was enlarged and the adhesions strong, he would prefer to do the operation in two parts. He operated sixteen years ago on a woman with tuberculosis of the kidney who is still alive. Her bladder symptoms have remained, but they are not so severe as they were when she had her tubercular kidney.

This matter is looked on too lightly. It is said that the bladder symptoms entirely disappear after the removal of the kidney, but Dr. Frank's observations are that the bladder symptoms remain, although they gradually wear away in time in a limited number of cases. The bladder having been accustomed to empty itself so frequently that this symptom does not disappear at once. Dr. Frank thinks that if an early diagnosis can be made before the bladder has acquired this habit of emptying itself frequently, the troublesome cystitis after nephrectomy would be very rare. With the aid of the cystoscope early diagnosis should be easy. In all large cities there are means of catheterizing the ureters and if a tuberculous kidney is found it should be removed at once.

Dr. J. G. Sherrill said that he always tries to determine the condition of the function of the other kidney before the operation. It is urged by many that the catheter should not be passed through an infected bladder into a sound ureter. There are many cases in which much can be learned by passing the catheter into the ureter, and if the bladder has normal mucous membrane it is perfectly safe to pass a catheter into the sound side. If the two urines are examined the presence of bacilli, as well as the ability of the kidney to take care of the function, can readily be determined. Recently Wright and Killmer have advised a new method of determining the efficiency of the kidney, a method of hemolysis. Dr. Sherrill said that he feels sure that injecting carbolic acid into the ureter would be a good proceeding if the ureter is but little if any affected, but if it is extensively diseased it would not be successful. The symptoms referable to the bladder are important, and many of the cases start with dysuria and polyuria. This is a very important point. The dysuria and polyuria are caused by the pus in the urine and should lead us to search for Koch's bacilli, and if found this proves the trouble to be tuberculosis. Bladder tuberculosis may be excluded by cystoscopy. If the urine is acid and contains pus it is important. Dr. Sherrill does not search one specimen many times, but many specimens a few times on succeeding days. Persistent search day after day for a week or more will usually result in finding the bacteria in the urine.

BRAIN INJURIES.*

D. C. PEYTON, M.D.

JEFFERSONVILLE, IND.

To determine whether or not immediate operative interference in brain injuries is indicated is a question of such serious magnitude as to require the most careful consideration of each individual case as it presents itself. Not infrequently, the life of the patient is in the balance, and his fate is determined by our decision one way or the other. The variety of symptoms presented in this class of cases is so great as to prove most perplexing to the minds of the ablest surgeons, many of whom have found at the autopsy that they have been in error in their diagnosis and decision. I feel fully warranted, therefore, in presenting a few facts as I have found them in the operating room and elsewhere, with the hope that the experience herein related may be the means of eliciting such discussion as will throw further light on the class of cases that has caused me great perplexity in trying to determine the advisability of an operation. It is my purpose to discuss this question from a surgical standpoint alone.

There can be no doubt that there is, and always will be, a distinct field for elective brain surgery. It would, indeed, be most unfortunate should there be a tendency to abandon so fertile a field for such brilliant achievements of surgical skill and such good to suffering humanity. Brain surgery has been so firmly established in recent years, however, that there is little danger now of its position being disturbed.

The symptoms which immediately follow injury to the brain are exceedingly important on account of their diagnostic value in determining the extent and nature of the lesion, and serve to aid in treatment and prognosis. It must not be forgotten, however, that the early symptoms may be misleading, and may not, by any means, reveal the exact nature of the injury. It sometimes happens that the most serious intracranial lesions may be found to exist in the presence of symptoms which would suggest only a slight concussion, while, on the other hand, a patient may quickly recover from an injury the early symptoms of which are so aggravated as to give the surgeon serious concern. The first symptom generally observed in serious head injuries is unconsciousness. It is not easy to determine the full significance of this from the symptom alone. In this connection, the most important question to determine is whether the unconsciousness is due to hemorrhage or to concussion or contusion of the brain. It is also of the utmost importance to know the manner in which the injury was received.

The symptom of unconsciousness alone will not reveal whether it is due to hemorrhage or concussion (unless the hemorrhage be from a cerebral artery, as in apoplexy) and as the hemorrhage due to injury is generally meningeal, it does not produce the degree of coma of a cerebral hemorrhage. The manner of approach of the unconsciousness is a most important diagnostic symptom; it is important to know if unconsciousness occurred immediately, after a few minutes or an hour or two, or if there was a return of consciousness after a primary loss, followed shortly by a reappearance of the former state. As a rule, when the patient has fallen from a height, striking on his head, serious lesion at the base of the brain may be expected; or a direct blow may be received on the convex surface of the skull, in such a manner as to produce a lesion in the cortical or subcortical substance, which will cause loss of consciousness. It is important to know the nature and location of the injury. It may be known that a man has received a blow on his head, but when first observed by the surgeon, the external evidences of the injury may have been so completely obliterated, or may not have existed at all, or may be of such a character as not to reveal the location of the blow, and unless there are present pressure symptoms, or other focal evidences, the surgeon may be deceived as to what has really taken place in the cranial cavity. While this state of false security lasts he patiently waits for a return of consciousness, while an increasing hemorrhage goes on within the cranial cavity. An increasing hemorrhage, of course, produces pressure unconsciousness. If the pressure is caused by a depressed fracture, examination will disclose the fact, and if there are marks of violence over the region of the middle meningeal artery, the fact should aid in the diagnosis. If it is determined that the early symptoms of the lesion are caused by a rupture of a meningeal artery, especially of the middle meningeal, the immediate effects may be regarded as most serious, unless relieved by prompt surgical procedure.

The success in a measure will depend on the surgeon's knowledge of cerebral localization. He must be able to determine with accurancy the location of a clot or lesion, or his surgical skill will fail in giving relief to the patient. He must know that on the cortex of the brain there are certain areas, not necessarily coextensive with either lobes or convolutions, these centers are the visual, the speech, the auditory, the sensorimotor, and the centers of sensation, smell and taste. Cerebral localization has to do mainly with two fissures—the fissure of Rolando and the fissure of Sylvius. A knowledge of these areas aids greatly in determining the location of a blood clot, or other brain lesion, and with more exact methods of localization, with more precise craniocerebral topographical methods, and with constantly improving surgical technic, the percentage of successes has been increased. The readiness with which the surgeon recognizes the emergency, and the promptness with which he operates, has contributed no little to this success.

---

* Read before the Indiana State Medical Association at West Baden-French Lick, 1905.

Fracture of the vault is usually the result of direct violence applied over a limited surface. When violence is attended by much momentum, the force is diffused, and a fissure will usually be found to travel from the point of primary inception to some distant region. A quick, sharp blow produces a local fracture, while violence with momentum produces a fissure. It is difficult to formulate a rule by which the direction traveled by these fractures can be determined. Direct violence to the vault from without results in a larger area of damage to the inner table than to the outer; and rarely, the amount of violence may be sufficient to break the inner table without fracture to the outer. The blow may not result in fracture of either table, yet the vibratory change in the shape of the vault results in a rupture of a vessel, with consequent hemorrhage, or it may result in actual contusion of the brain substance and displacement of cerebrospinal fluid and blood.

Again, we may have a transmission of the force to the opposite side of the vault from the point of the receipt of the injury, resulting in fracture by *contrecoup*. Whether this transmission of force is the result of the wave current, or whether it travels by other means to reach the opposite side of the skull, we are certain of the fact that in some way the force of the blow is transmitted to the opposite side, resulting either in fracture or other injuries.

The length of time that may elapse from the receipt of brain injury until active diagnostic symptoms appear, is indefinite, and may vary from a few minutes to several hours or many days.

Borel, as early as 1677, described a class of symptoms or disturbances the result of contusion of the head, which was neither dependent on a fracture of the bone nor a tear of the blood vessels, but was so transitory and of such slight intensity that an actual wounding of the brain could not be its underlying cause. Later when autopsies were more often made on patients dying from injuries of the head, a question arose which has only recently been answered. Following the most dangerous and severe brain symptoms the most careful autopsy failed to reveal the slightest trace of visible change in the brain of the deceased. In other patients, in whom all brain symptoms were absent, and in whom neither the motor nor the sensory functions had suffered, it was found extensive brain lesions existed, frequently a large portion of the frontal lobe was found crushed to a pulp. It is necessary, therefore, that physicians be extremely guarded in their diagnosis and prognosis in these injuries.

That surgical interference is imperative in these cases there can be no doubt. In a condition of hemorrhage of a typical character there are three consecutive stages that must be recognized, namely: First, a partial or complete unconsciousness, the result of stunning from a blow; second, the recovery from this, and later a secondary unconsciousness coming on either slowly or with marked rapidity, as the result of pressure from a slowly accumulating hemorrhage; third, unconsciousness occurring as the result of an overwhelming hemorrhage, forming a veritable wet blanket over the brain. It is well to remember, however, that in the case of a rupture of a large branch, and especially the main branch of the middle cerebral, there will be such a rapid outpouring of blood as totally to obliterate the period of consciousness between the two stages.

Hemorrhage may be extradural or intradural, following a blow on the skull, with or without fracture, fissured or depressed. The frequency of hemorrhage in intracranial injury is quite marked. Phelps holds that in from 50 to 60 per cent. of the cases this factor occurs in sufficient quantity and such relation as materially to influence the final result, and to serve as a determinate factor of the symptoms; and that in about one-third of all cases it was either the direct or the sole cause of a fatal ending.

Operative interference is indicated when there are symptoms of compression, whether from hemorrhage, depressed bone, or the presence of a foreign body. The greatest mortality is in injuries caused by falls from a height, striking on the head, such as being thrown from a horse, or falling from a building or scaffold. Gunshot wounds of the brain are almost equally fatal. In determining the question as to whether or not operative interference is indicated, it is necessary that the manner of receipt of the injury, the character of symptoms following, and the rapidity with which certain symptoms come on following the accident, be taken into consideration. If called on to assume the responsibility of a patient presenting such evidences of serious brain lesion as paralysis in some form, clonic convulsions of one side or the other, inequality of the pupils, with possibly unconsciousness or profound coma, and probably with Cheyne-Stokes or stertorous respiration, there is little doubt that the surgeon will readily recognize that surgical interference is imperatively demanded. I desire to emphasize the fact that, in my judgment, the danger to the patient of an exploratory opening with an observance of the highest degree of aseptic technic, is infinitely less than the unreasonable delay that is frequently permitted while waiting for definite diagnostic symptoms. It is in that class of borderline cases presenting only a few of the foregoing symptoms, and maybe in an exceedingly mild form, or in the cases in which it is necessary to depend for diagnosis largely or wholly on the manner of receipt of the injury, together with its character and location, that we are liable to be misled by an apparently unimportant array of symptoms, and to fall short of our duty as surgeons by failing to recognize at the earliest possible time the unusual symptoms pointing to a lesion at some point in the brain that could and should be relieved by operative interference. I would urge, therefore, the importance of the physician observing in detail each case of brain injury from the time of his first visit until such a time as he can reasonably assure himself that no injury has occurred within the cranial walls. It is not intended by any means to sacrifice conservatism, but rather to increase its usefulness by adding to it that degree of conservative boldness born of a knowledge of imperative duty, enhanced by a knowledge of anatomy of the brain, together with the significance of a class of symptoms, and the ability to apply the highest degree of surgical technic for the relief of this class of patients.

In this connection, the following report of two cases will be of interest in illustrating in a manner some of the statements contained herein:

Case 1.—Three years ago I was called to attend a man aged 35, of remarkably strong physique, who, while in a fight, had been shot with a 38-caliber ball from a pistol. The bullet entered the skull from behind and well up toward the top in about the median line.

Examination.—It was found that the skull had been literally crushed for a space of an inch or an inch and a half in diameter. The dura was badly lacerated, and many fragments of bone were found approximately two inches down in the brain substance; there was also extensive laceration of the brain tissue.

Treatment.—These fragments of bone were removed, and the wound in the brain carefully but thoroughly irrigated with a normal saline solution, quite a quantity of the brain matter escaping. The dura was sutured as well as possible, the external wound closed and dressed and the patient put to bed.

Result.—The man made an uninterrupted recovery, and at the end of ten days was able to sit up, and in two weeks left the hospital apparently all right. The only symptom that showed itself following the operation was on the second day, when the man called attention to the fact that he felt something under his back and asked if it could be removed. On investigation it was found that he was lying on his left hand, of which he was totally unconscious so far as the hand was concerned, showing conclusively that the arm center in the brain had been slightly interfered with. This symptom lasted for only a few days, when it cleared up. The man was a coal-shoveler on the fleets, and the last heard of him, about a year ago, he was perfectly well and had suffered no inconvenience from his injury.

Case 2.—A man, while engaged in repairing an electric light wire one day last winter, fell from a scaffold to the frozen ground, a distance of probably twenty-five feet, striking on the left side of his head. The only external evidence of an injury was a slight contusion of the scalp on the left side.

Examination.—When seen a few minutes after the injury he presented the following symptoms: Total loss of consciousness, inequality of pupils, the left being more dilated than the right, with slight conjugate deviation of the eyes toward the left; ecchymosis around the left eye, with considerable protrusion of the left eyeball; irregular pulse, and a slight tendency to Cheyne-Stokes respiration. There was a fracture of the left arm and left leg, which interfered materially with diagnosing any paralysis which might have followed the injury. Later it was observed that there was variation in the pupils, the left pupil contracting somewhat, with a slight dilatation of the right. Within twenty or thirty minutes following the accident he showed marked clonic contractions, or convulsions of both the arm and leg on the right side. The knee-jerk was slightly exaggerated on the right, while on the left the result was negative on account of the fracture of the thigh. It was difficult to test his sensory reflexes on account of his profound unconsciousness.

Treatment.—Injury of the left side, probably extensive hemorrhage from the left meningeal artery, was diagnosed, and it was decided to trephine. There appeared to be no injury to the vault of the skull whatever, both tables being intact. The opening was made a little anterior to the junction of the temporal, parietal and frontal bones on the left side. There was no extradural hemorrhage, although the dura appeared very tense. On opening the dura it was found that there was some extravasation of blood under the membrane which had followed the convolutions of the brain at this point. Simultaneously with the opening of the dura and the relief of the tension the patient's pulse and respiration became very much improved under the anesthetic. The wound was irrigated with a normal saline solution, the dura sutured, and the external wound closed. The improvement in the patient's condition continued, and was even more marked for twelve or fifteen hours following the operation, when he developed what appeared to be traumatic pneumonia, from which he quickly died.

Autopsy.—The autopsy showed some laceration of the brain tissue, with rather extensive extravasation of blood at several points, and with a stellate fracture at the base, beginning at the junction of the anterior wing of the sphenoid and frontal bones, running backward through the middle fossa to the petrous portion of the temporal bone, and another line of fracture beginning at the same point and running forward through the floor of the orbit, and a third fracture line running through the cribriform plate of the ethmoid and crossing to the opposite side.

I have purposely refrained from taking up at length the various means or instruments suggested for gaining an entrance into the brain. It is believed that each of these various instruments has its advantages in certain cases and its disadvantages in others. This question has been so fully and ably discussed by such men as Keen and Mills and others that it seems unnecessary to consider it except in a general way. In brain tumors or in other diseased conditions, I am partial to the chisel and mallet. In brain injuries with laceration and probably wounded vessels with consequent hemorrhage, the trephine and the rongeur are to be preferred, lest by the use of the chisel and mallet a further injury to the already contused or lacerated brain is had, or an already dangerous hemorrhage from a wounded vessel is increased. These, however, are questions to be determined by the operator when he assumes the management of each individual case as it presents itself.

FURTHER REMARKS ON THE MODE OF INFECTION IN UNCINARIASIS.*

CLAUDE A. SMITH, M.D.

Pathologist to Grady Hospital, Baptist Tabernacle Infirmary, Professor of Pathology and Bacteriology, Southern Dental College; Demonstrator of Pathology, Atlanta College of Physicians and Surgeons; Secretary Anatomical Board of Georgia.

ATLANTA, GA.

At the session of this Association at Atlantic City last year I presented a report of an experiment on a human being to determine whether the larvæ of the uncinaria would penetrate the skin. At that time I reported that, after placing soil containing larvæ on the skin of an individual, an eruption had followed, and that, after a period of seven weeks, the eggs of the uncinaria were found in the feces.

In this paper I report a second experiment, similar to the first, in which the soil containing the larvæ was placed on the wrist of an individual who had shortly before been discharged from the hospital after an operation for hernia, and the eggs of the uncinaria were found in the feces during the sixth week afterward.

In the first case, it was not feasible to obtain photographs of the various stages of the eruption produced on the skin by the larvæ, but in this second case I was able to do this, and present them in the report which follows:

METHOD OF PROCEDURE.

Preliminary Arrangements.—After making arrangements with the patient regarding the experiment, a specimen of feces was obtained containing an abundance of the eggs of the uncinaria. Some soil was next obtained and baked for an hour so as to eliminate any other organism. After cooling this soil, the feces containing the eggs were then mixed with it until the odor of the feces had about disappeared, sufficient water being added to render the mass slightly damp. This mixture was then placed in Petri dishes and kept at the room temperature.

---

* Read at the joint meeting of the Section on Practice of Medicine and the Section on Pathology and Physiology at the Fifty-sixth Annual Session, July, 1905.

At the end of twenty-four hours an examination of the soil showed that the eggs had all hatched out, as no eggs could be found, but there was an abundance of the young larvæ.

Application to Skin.—An important point to be determined was the age at which the larvæ would penetrate the skin. It was decided, therefore, to place the larvæ on the skin every day from the time they were twenty-four hours old until some result was obtained. Accordingly when these larvæ were twenty-four hours old some of the soil was placed on the wrist, wrapped with a plain gauze bandage and allowed to remain for one hour. At the end of this time the soil was removed and the wrist examined. No effect was apparent and the patient said he had experienced no sensation during the period.

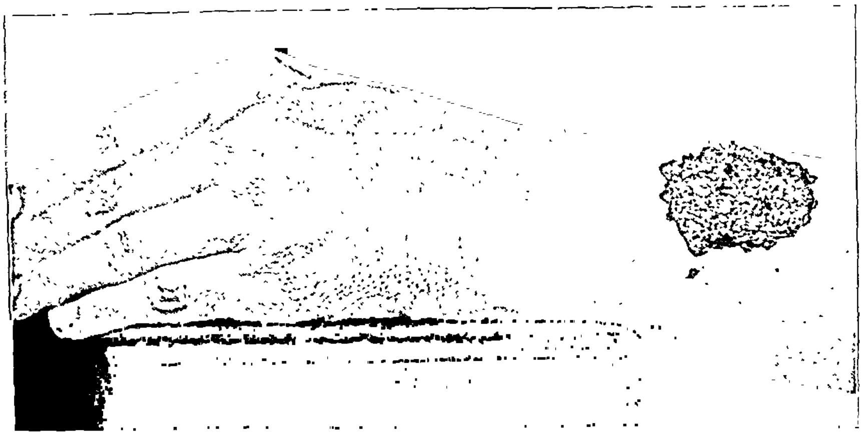

Fig. 1.—The soil containing the larvæ as it appeared on the wrist, the tendons and veins of the hand showing distinctly.

This procedure was repeated when the larvæ were forty-eight hours old, and again on the third, fourth and fifth days. No result whatever was obtained, and this was rather surprising, as the results in the previous experiment were obtained when the larvæ were four days old.

On the sixth and seventh days the patient failed to appear, but he reappeared on the eighth day, and the soil was again bound on the wrist and allowed to remain for one hour.

Within five minutes after the soil was placed on the wrist the patient complained of a sharp, stinging sensation in the area covered by the soil, which increased and persisted during the time the soil was allowed to remain on the wrist. At no time was the wrist of the patient given any treatment whatever before applying the soil. The soil was simply placed directly on the skin, as shown in Figure 1. (About the third day a simple ointment was placed on the eruption to relieve the anxiety of the patient.)

Treatment of Wrist.—After remaining on the wrist for one hour the soil was removed, and on inspection the entire area was found to be decidedly reddened. The soil was thoroughly removed and the wrist was then carefully wrapped with a number of layers of plain gauze bandage, and the patient was instructed not to remove this and to return the following day.

On coming back the next day, the patient said that the stinging sensation had gradually subsided the day previous, but that during the night the intense itching of the area was so annoying as to interfere with his sleep. On removing the bandage from the wrist the redness over the area was increased, the area was slightly elevated, and the entire dorsum of the wrist was swollen. The patient was instructed to restrain any desire to scratch the area, but to be sure that the area would not be damaged by the finger nails of the patient while asleep the layers of gauze bandage were replaced.

Constitutional and Local Symptoms.—On returning the day following, the patient stated that he had slept scarcely any at all the night before on account of the excruciating itching, and that he had rolled and tossed all night.

Removal of the bandage showed the wrist greatly swollen, the swelling extending downward over the back of the hand and upward a short distance on the forearm. The area which had been covered by the soil was intensely reddened, and vesicles covered the entire area. On direct pressure, however, the patient said that there was very little tenderness. The lack of tenderness was a marked feature throughout the course of the eruption. This was true in the first case. The condition of the wrist at this time is shown in Figure 2.

On the third day of the eruption, the swelling had extended down over the first phalanx of the fingers and upward to about half way to the elbow. The swelling reached its height at this time. The vesicle had become confluent, forming large blebs, and the redness was more intense. The itching was still severe, but the patient said he had rested better than on the two previous nights. There was some redness up the inner side of the forearm, but no involvement of the axillary glands.

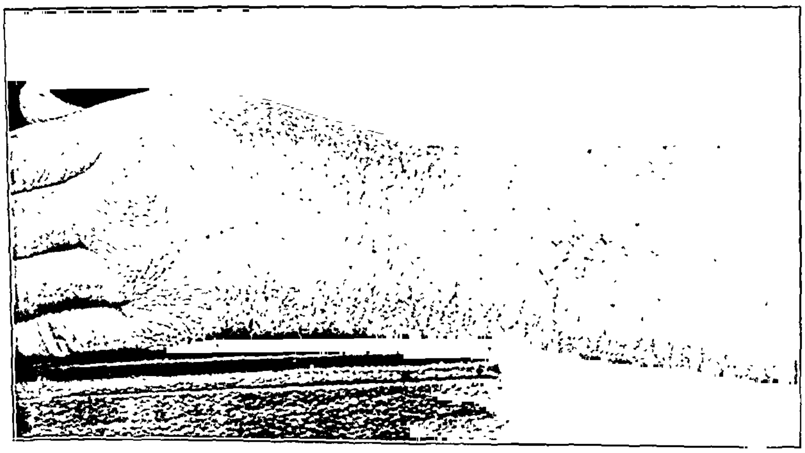

Fig. 2.—Showing swelling of wrist, obliterating veins and tendons of hand and vesicle formation.

On the fourth day, some of the vesicles had ruptured, moistening the bandage, and the swelling had begun to recede. The patient had rested much better than previously. The itching had also decreased in severity.

On the fifth day, many of the vesicles had ruptured, and a crust had formed over a part of the area. The swelling had greatly decreased, the veins and tendons showing well through the skin. Previously they had been obliterated by the swelling. The patient now said

In this connection, the following report of two cases will be of interest in illustrating in a manner some of the statements contained herein:

Case 1.—Three years ago I was called to attend a man aged 35, of remarkably strong physique, who, while in a fight, had been shot with a 38-caliber ball from a pistol. The bullet entered the skull from behind and well up toward the top in about the median line.

Examination.—It was found that the skull had been literally crushed for a space of an inch or an inch and a half in diameter. The dura was badly lacerated, and many fragments of bone were found approximately two inches down in the brain substance; there was also extensive laceration of the brain tissue.

Treatment.—These fragments of bone were removed, and the wound in the brain carefully but thoroughly irrigated with a normal saline solution, quite a quantity of the brain matter escaping. The dura was sutured as well as possible, the external wound closed and dressed and the patient put to bed.

Result.—The man made an uninterrupted recovery, and at the end of ten days was able to sit up, and in two weeks left the hospital apparently all right. The only symptom that showed itself following the operation was on the second day, when the man called attention to the fact that he felt something under his back and asked if it could be removed. On investigation it was found that he was lying on his left hand, of which he was totally unconscious so far as the hand was concerned, showing conclusively that the arm center in the brain had been slightly interfered with. This symptom lasted for only a few days, when it cleared up. The man was a coal-shoveler on the fleets, and the last heard of him, about a year ago, he was perfectly well and had suffered no inconvenience from his injury.

Case 2.—A man, while engaged in repairing an electric light wire one day last winter, fell from a scaffold to the frozen ground, a distance of probably twenty-five feet, striking on the left side of his head. The only external evidence of an injury was a slight contusion of the scalp on the left side.

Examination.—When seen a few minutes after the injury he presented the following symptoms: Total loss of consciousness, inequality of pupils, the left being more dilated than the right, with slight conjugate deviation of the eyes toward the left; ecchymosis around the left eye, with considerable protrusion of the left eyeball; irregular pulse, and a slight tendency to Cheyne-Stokes respiration. There was a fracture of the left arm and left leg, which interfered materially with diagnosing any paralysis which might have followed the injury. Later it was observed that there was variation in the pupils, the left pupil contracting somewhat, with a slight dilatation of the right. Within twenty or thirty minutes following the accident he showed marked clonic contractions, or convulsions of both the arm and leg on the right side. The knee-jerk was slightly exaggerated on the right, while on the left the result was negative on account of the fracture of the thigh. It was difficult to test his sensory reflexes on account of his profound unconsciousness.

Treatment.—Injury of the left side, probably extensive hemorrhage from the left meningeal artery, was diagnosed, and it was decided to trephine. There appeared to be no injury to the vault of the skull whatever, both tables being intact. The opening was made a little anterior to the junction of the temporal, parietal and frontal bones on the left side. There was no extradural hemorrhage, although the dura appeared very tense. On opening the dura it was found that there was some extravasation of blood under the membrane which had followed the convolutions of the brain at this point. Simultaneously with the opening of the dura and the relief of the tension the patient's pulse and respiration became very much improved under the anesthetic. The wound was irrigated with a normal saline solution, the dura sutured, and the external wound closed. The improvement in the patient's condition continued, and was even more marked for twelve or fifteen hours following the operation, when he developed what appeared to be traumatic pneumonia, from which he quickly died.

Autopsy.—The autopsy showed some laceration of the brain tissue, with rather extensive extravasation of blood at several points, and with a stellate fracture at the base, beginning at the junction of the anterior wing of the sphenoid and frontal bones, running backward through the middle fossa to the petrous portion of the temporal bone, and another line of fracture beginning at the same point and running forward through the floor of the orbit, and a third fracture line running through the cribriform plate of the ethmoid and crossing to the opposite side.

I have purposely refrained from taking up at length the various means or instruments suggested for gaining an entrance into the brain. It is believed that each of these various instruments has its advantages in certain cases and its disadvantages in others. This question has been so fully and ably discussed by such men as Keen and Mills and others that it seems unnecessary to consider it except in a general way. In brain tumors or in other diseased conditions, I am partial to the chisel and mallet. In brain injuries with laceration and probably wounded vessels with consequent hemorrhage, the trephine and the rongeur are to be preferred, lest by the use of the chisel and mallet a further injury to the already contused or lacerated brain is had, or an already dangerous hemorrhage from a wounded vessel is increased. These, however, are questions to be determined by the operator when he assumes the management of each individual case as it presents itself.

FURTHER REMARKS ON THE MODE OF INFECTION IN UNCINARIASIS.[*]

CLAUDE A. SMITH, M.D.

Pathologist to Grady Hospital, Baptist Tabernacle Infirmary, Professor of Pathology and Bacteriology, Southern Dental College; Demonstrator of Pathology, Atlanta College of Physicians and Surgeons; Secretary Anatomical Board of Georgia.

ATLANTA, GA.

At the session of this Association at Atlantic City last year I presented a report of an experiment on a human being to determine whether the larvæ of the uncinaria would penetrate the skin. At that time I reported that, after placing soil containing larvæ on the skin of an individual, an eruption had followed, and that, after a period of seven weeks, the eggs of the uncinaria were found in the feces.

In this paper I report a second experiment, similar to the first, in which the soil containing the larvæ was placed on the wrist of an individual who had shortly before been discharged from the hospital after an operation for hernia, and the eggs of the uncinaria were found in the feces during the sixth week afterward.

In the first case, it was not feasible to obtain photographs of the various stages of the eruption produced on the skin by the larvæ, but in this second case I was able to do this, and present them in the report which follows:

METHOD OF PROCEDURE.

Preliminary Arrangements.—After making arrangements with the patient regarding the experiment, a specimen of feces was obtained containing an abundance of the eggs of the uncinaria. Some soil was next obtained and baked for an hour so as to eliminate any other organism. After cooling this soil, the feces containing the eggs were then mixed with it until the odor of the feces had about disappeared, sufficient water being added to render the mass slightly damp. This mixture was then placed in Petri dishes and kept at the room temperature.

---

[*] Read at the joint meeting of the Section on Practice of Medicine and the Section on Pathology and Physiology at the Fifty-sixth Annual Session, July, 1905.

At the end of twenty-four hours an examination of the soil showed that the eggs had all hatched out, as no eggs could be found, but there was an abundance of the young larvæ.

Application to Skin.—An important point to be determined was the age at which the larvæ would penetrate the skin. It was decided, therefore, to place the larvæ on the skin every day from the time they were twenty-four hours old until some result was obtained. Accordingly when these larvæ were twenty-four hours old some of the soil was placed on the wrist, wrapped with a plain gauze bandage and allowed to remain for one hour. At the end of this time the soil was removed and the wrist examined. No effect was apparent and the patient said he had experienced no sensation during the period.

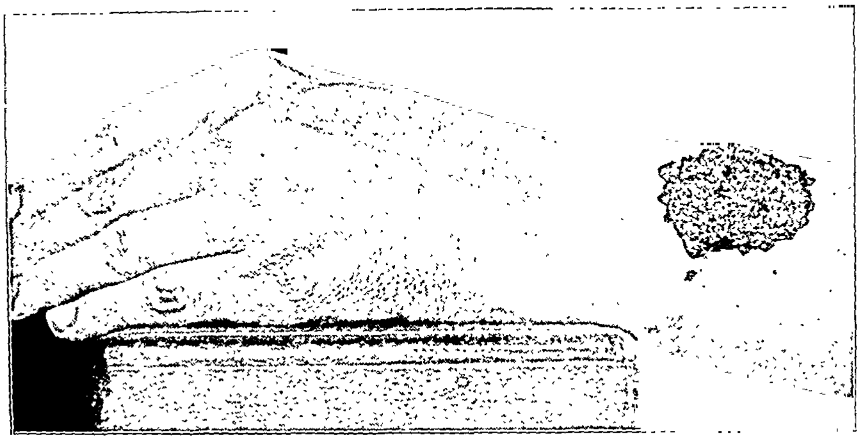

Fig. 1.—The soil containing the larvæ as it appeared on the wrist, the tendons and veins of the hand showing distinctly.

This procedure was repeated when the larvæ were forty-eight hours old, and again on the third, fourth and fifth days. No result whatever was obtained, and this was rather surprising, as the results in the previous experiment were obtained when the larvæ were four days old.

On the sixth and seventh days the patient failed to appear, but he reappeared on the eighth day, and the soil was again bound on the wrist and allowed to remain for one hour.

Within five minutes after the soil was placed on the wrist the patient complained of a sharp, stinging sensation in the area covered by the soil, which increased and persisted during the time the soil was allowed to remain on the wrist. At no time was the wrist of the patient given any treatment whatever before applying the soil. The soil was simply placed directly on the skin, as shown in Figure 1. (About the third day a simple ointment was placed on the eruption to relieve the anxiety of the patient.)

Treatment of Wrist.—After remaining on the wrist for one hour the soil was removed, and on inspection the entire area was found to be decidedly reddened. The soil was thoroughly removed and the wrist was then carefully wrapped with a number of layers of plain gauze bandage, and the patient was instructed not to remove this and to return the following day.

On coming back the next day, the patient said that the stinging sensation had gradually subsided the day previous, but that during the night the intense itching of the area was so annoying as to interfere with his sleep. On removing the bandage from the wrist the redness over the area was increased, the area was slightly elevated, and the entire dorsum of the wrist was swollen. The patient was instructed to restrain any desire to scratch the area, but to be sure that the area would not be damaged by the finger nails of the patient while asleep the layers of gauze bandage were replaced.

Constitutional and Local Symptoms.—On returning the day following, the patient stated that he had slept scarcely any at all the night before on account of the excruciating itching, and that he had rolled and tossed all night.

Removal of the bandage showed the wrist greatly swollen, the swelling extending downward over the back of the hand and upward a short distance on the forearm. The area which had been covered by the soil was intensely reddened, and vesicles covered the entire area. On direct pressure, however, the patient said that there was very little tenderness. The lack of tenderness was a marked feature throughout the course of the eruption. This was true in the first case. The condition of the wrist at this time is shown in Figure 2.

On the third day of the eruption, the swelling had extended down over the first phalanx of the fingers and upward to about half way to the elbow. The swelling reached its height at this time. The vesicle had become confluent, forming large blebs, and the redness was more intense. The itching was still severe, but the patient said he had rested better than on the two previous nights. There was some redness up the inner side of the forearm, but no involvement of the axillary glands.

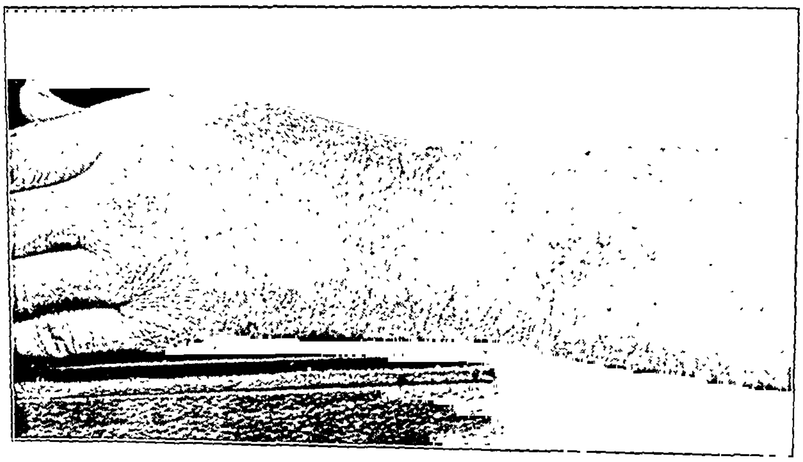

Fig. 2.—Showing swelling of wrist, obliterating veins and tendons of hand and vesicle formation.

On the fourth day, some of the vesicles had ruptured, moistening the bandage, and the swelling had begun to recede. The patient had rested much better than previously. The itching had also decreased in severity.

On the fifth day, many of the vesicles had ruptured, and a crust had formed over a part of the area. The swelling had greatly decreased, the veins and tendons showing well through the skin. Previously they had been obliterated by the swelling. The patient now said he was feeling all right again. Figure 3 shows the hand at this time.

On the sixth day, almost the entire area was covered by the crust which had formed, only a few vesicles remaining. Only a trace of the swelling remained about the wrist, and the patient said that the slight itching sensation which remained was not confined to the area of the eruption, but was scattered over the entire forearm.

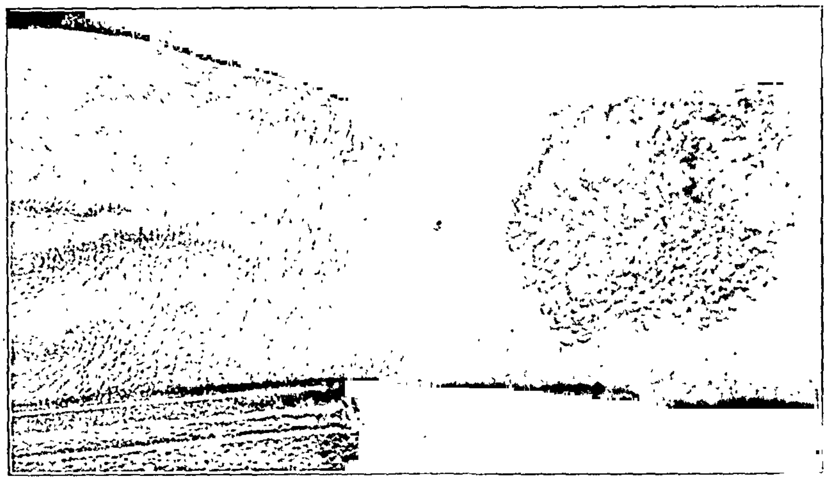

Fig. 3.—Showing the large crust forming over the area and the decrease of the swelling.

On the eighth day, the crusts which had formed over the area had begun to scale off, the swelling was practically all gone, and the patient said that he felt about normal again.

Examination of Feces.—The feces of this patient were carefully examined at the beginning of this experiment, the feces being washed and centrifugated, as by this method I have found that it is possible to detect the slightest infection with uncinaria, but no eggs of the uncinaria were found. After beginning the experiment, the feces were examined twice a week, but with negative results until the middle of the sixth week after the soil was placed on the wrist. At this time a few of the eggs of the uncinaria were found in the feces, and after this they steadily increased in number.

As this patient was just out of the hospital after an operation, no examination of the blood was made, as under the circumstances this was considered to be of such uncertain value as not to be worth while.

Soon after the appearance of the eggs in the feces, in reply to questions, the patient said that his bowels were inclined to be loose, and a week or so later this had increased to a mild diarrhea. This cleared up in a week or so more, and the patient said his stools were normal.

Eight weeks after the appearance of the eggs of the uncinaria in the feces of the patient, he was given the usual treatment to remove the parasite, i. e., two doses of thymol of 30 grains each, preceded and followed by a large dose of salts. All the stools were saved for twenty-four hours following the treatment, and these were carefully washed and examined. As a result, 596 adult male uncinaria and 752 female uncinaria were found, making a total of 1,348.

Some time after this the feces of the patient were again examined and found still to contain a few eggs of the uncinaria. Since then he has been given the treatment at two different times, but at the present time still has a slight infection.

SUMMARY.

In the criticisms of the experiments of Looss, Pieri, the assistant of Grassi,[1] states that the experiments of Looss are uncertain, because Looss can not be sure that the infection in his case was not through the mouth on account of his having handled the larvæ so much.

In this last experiment performed by me, I took great pains to be sure that the patient could not come in contact with the larvæ at any other time than when placed on the wrist by me, and the fact that such an enormous number were found in the intestines would discredit any idea that the infection was through the mouth, as mentioned by Pieri.

The deductions from these experiments, I think, are plain. That the disease is contracted through the skin is suported by the clinical observations which I have reported previously. That this is the only way in which the disease is contracted I am not sure, but it appears to be the mode of infection in the great majority of instances.

These experiments also show that the eruption has no tendency to spread when it is not disturbed by scratching and has a duration of only a few days. When the eruption occurs under natural conditons, however, the individual scratches and tears the eruption, infecting the entire area and spreading the infection over a large additional area, and as a result of this the eruption is often weeks in healing up.

A study of the climatic conditions I find to be of value in determining just when and under what conditions these larvæ penetrate the skin in the natural conditions. These observations have not yet been completed. I hope to be able to report on them later.

Last year I reported some examinations of tissue which had been subjected to the larvæ, but in which I had not been able to locate the larvæ. These experiments I have not had an opportunity to repeat, and, therefore, they are still uncompleted.

DISCUSSION.

Dr. Richard C. Cabot, Boston, said that two great medical achievements have resulted from the war with Spain. We have freed Cuba of yellow fever and we are now freeing Porto Rico from uncinariasis. To Capt. Baily K. Ashford, U. S. A., and Lieut. W. W. King, U. S. P. H. and M. H. S., we owe much of what has been done. They have conducted a field campaign against the disease among the whole people of Porto Rico. They have field hospitals, tents, etc., which they take from town to town; they camp outside the towns and there they treat the population. The people come

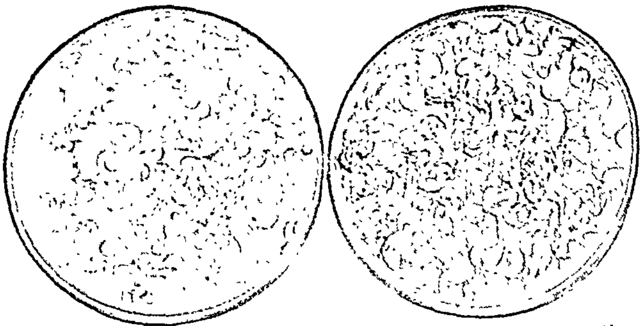

Fig. 4.—Shows 1348 uncinaria removed from the intestines twelve weeks after the eruption on the wrist.

down to them to be treated. When they have intense anemias to deal with the patients are treated in bed, while those with milder cases take the medicine given them and go home. Every case is diagnosed by means of the microscope, the stools and blood being carefully studied. Two American physicians have organized and pushed a plan to treat practically the entire population of Porto Rico. Dr. Ashford and Dr. King are engaged in this work now, as they have been for a number of months. They were invited to be present at this meeting, but they were detained in the service, and are even now engaged in their splendid work. They ask nothing from us, but their fine service certainly demands from us knowledge of the work and our sympathy. The results have been published in brief, but not in detail in the journals, and are known less widely than they deserve. Dr. Cabot looks on their achievements as destined to be as beneficent as the work of Reed and Carrol on yellow fever in Cuba.

Dr. M. H. Fussell, Philadelphia, asked if Dr. Smith considers the ground itch as the only source of this parasite in the human being, or if the affection may occur by the parasite being swallowed, and whether he has any idea or made any calculations of how many embryos there may have been in the mass that he placed on the patient's wrist. Dr. Fussell understands that the embryo or parasite does not increase in the intestines of the individual. He said that he would also like to know if the blood was examined and the eosinophiles counted.

Dr. Philip King Brown, San Francisco, stated that in San Francisco physicians have experiences with three classes of uncinariasis. The first class came from Mexico, evidently a pure class. Then came soldiers, returning from the Philippines, without having had any symptoms of uncinariasis before discharge. Some of them were kept in the general hospital with amebic infection, and were discharged, but nothing was known regarding the presence of uncinariasis. Many of these cases came to the county hospital. A peculiar thing about some of these soldiers was the striking symptoms that occurred when there were few parasites. Dr. Brown recalled one patient who came near dying of anemia and yet the physicians could find but seven parasites. The third class of cases was found among the Porto Ricans who were sent to the Hawaiian Islands to replace Japanese laborers on sugar plantations. They were not a success, and were returned to San Francisco, where a large majority of them still remain. They present the type of the disease which has been so thoroughly investigated by Ashford. Attempts have been made by Gunn of San Francisco, who has studied the cases in San Francisco very thoroughly, to find the parasite in infants born since these Porto Ricans left their native home, but thus far they have not been successful. He has, however, discovered several cases of bilharzia infection in these Porto Ricans.

Dr. Claude A. Smith, Atlanta, Ga., in reply to the questions stated that, while he can not say that the passage of the parasite through the skin is the only way by which it gains access to the human body, yet from the experiments and from the clinical history of the cases this mode of access appears to be the rule and the ingestion through the alimentary canal the exception. In growing the larvæ in the laboratory, it was noticed that they would climb on the sides of the vessel. This would cause us to suspect that they would climb on plants from their natural development in the soil, and if so, it is possible that they might be swallowed by persons eating raw vegetables. He said that it was impossible to count the number of larvæ contained in the soil which he placed on the wrist of the patient. They were intensely concentrated, more concentrated than they would ever develop under natural conditions. There were undoubtedly many thousands in the small amount of soil which he used, as examination under the microscope showed it to be swarming with them. Autoinfection, he said, is practically an impossibility. His experiments indicate that the larvæ will not attempt to enter the tissues before they are four or six days old, and it is not likely that the eggs would remain in the intestines for this length of time, even if they could find conditions suitable for hatching. As before stated, no blood examinations were made in this case, as the patient was just out of the hospital, and such examinations, therefore, would have been of uncertain value. Dr. Smith inclines to the view that the parasites pass into the veins and thus get into the circulation. In the experiments the inflammation of the forearms above the eruption appeared more as a phlebitis than a lymphangitis. The children of all classes in the South go barefoot in the summer, and all are subject to the ground itch, but it is most common among the poorer classes in the country. As the better classes are less exposed to the disease, they usually have a mild form which can only be diagnosed by the examination of the feces, and as there are no objective or subjective symptoms these cases are generally overlooked. It is only the severe cases which interfere with the development of the person and which present symptoms of the disease. Those individuals who have had only one or two attacks of ground itch have only a small number of the parasites in the intestines, and these produce no effect on the development of the person. It is only when there have been a number of attacks of ground itch (usually covering a period of several years) that there is any interference with the development of the body. A study of the climatic conditions shows that in many sections the conditions favorable to the development of the parasite occur only two or three times during a summer. When the conditions are favorable for the development of the parasite one will usually find every child of an entire family infected, but usually there is not more than one who has the severe type of the disease. In the majority of the cases of the severe type of the disease, the patient will eventually "outgrow" the disease; that is, the child will begin wearing shoes at 15 or 17 years of age, and from that time on the parasites gradually die out.

IRITIS TUBERCULOSA AS DIAGNOSED AND TREATED BY KOCH'S TUBERCULIN.[*]

WILLIAM E. GAMBLE, B.S., M.D.
Adjunct Professor Ophthalmology and Clinical Ophthalmology, University of Illinois; Ophthalmic Surgeon, Cook County Hospital, etc.

AND

E. V. L. BROWN, B.S., M.D.

CHICAGO.

HISTORY OF THE CASE TREATED.[1]

Patient.—Mr. M. E. S., a clerk, aged 25, consulted Dr. Gamble Aug. 27, 1904, on account of persistent "redness" of the left eye of four months' duration. At no time had there been severe pain. There was no personal history or evidence of syphilis, and the family history of tuberculosis was negative.

Examination.—This revealed ciliary injection and an irregular pupil which responded poorly to light and dilated irregularly under atropin with the exposure of numerous posterior synechia. A reddish growth the size of a pinhead was discovered springing from the inferior temporal root of the iris. With the aid of a Berger loupe, a second smaller growth was seen above the first and nearer the pupillary border of the iris. The nodes were semi-transparent and non-vascular. The iris itself was discolored, its markings indistinct and the media hazy. L. vision, 20/70, that of the fellow eye, 20/50 with no improvement by glasses. The patient had a slight cough, an afternoon temperature of 99.5 and slightly subnormal temperature; pulse, 80; weight, 117 pounds; he is able to be about his work every day.

A general examination by Prof. W. E. Quine reads as follows:

(a) Enlarged glands above the inner third of the left clavicle. (b) Leucopenia—only 3,500 whites—8 per cent. of them small mononuclear and 32 per cent. large mononuclear (i. e., 'relative' lymphocytosis). (c) A little cough without expectoration or discoverable pulmonary localization. Suggests involvement of the mediastinal glands. (d) No bacilli found in urine. Findings suggest glandular tuberculosis.

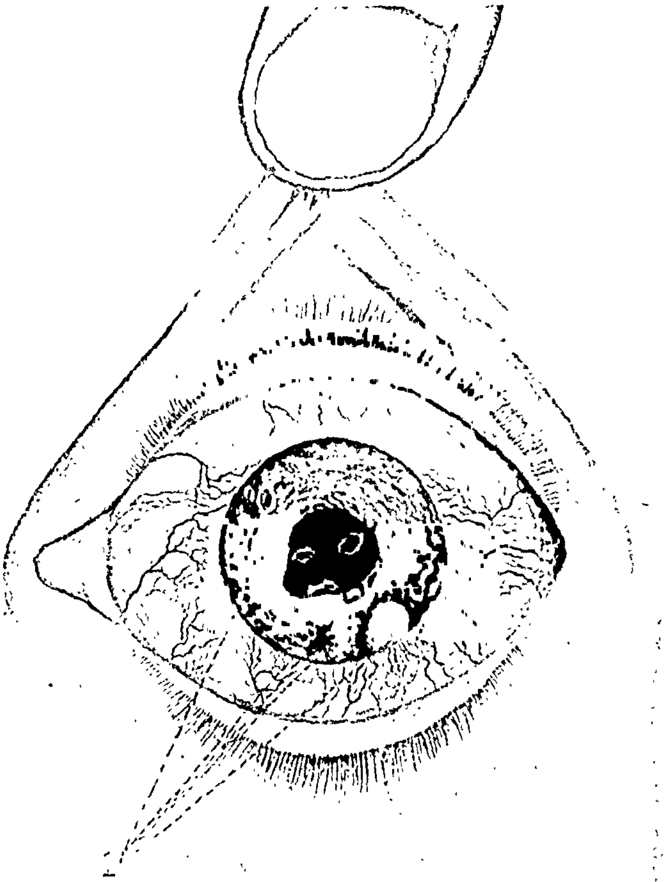
---

[*] Read in the Section on Ophthalmology of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

[1] This patient was shown before the Chicago Ophthalmological Society, Oct. 11, 1904, when the inflammation was at its most florid stage, and again six months later, March 14, 1905, after an apparent cure had been effected.

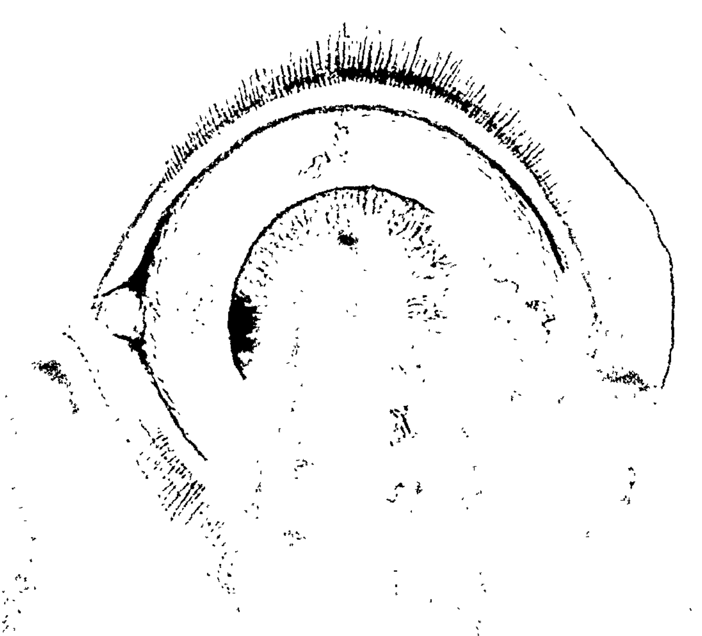
Six subsequent examinations of the sputum for tubercle bacilli were negative.

Treatment.—Commencing Sept. 7, 1904, potassium iodid and later mercurial inunctions were used for several weeks. The two nodes not only steadily increased in size and became grayish-opaque, but three additional nodes appeared in the lower nasal quadrant, ciliary injection became more marked and fine precipitates developed over the lower half of the posterior surface of the cornea. These precipitates were not arranged in the classical triangular shape characteristic of serous cyclitis but were spread over the entire lower segment without particular form and indicated rather an extension of



tinatum. The node lies at the lower end of a line drawn through axis 110 degrees, and measures 2.5 mm. in the vertical plane, 2 mm. in the horizontal and 2 mm. in the antero-posterior plane. At least its superior one-half rides free over the iris and obscures four-sevenths of the iris surface measured from the root toward the pupillary border. Four smaller nodes about the size of pinheads are seen, two of them seated in the sinus angle below, one nasal, and the fourth at the pupillary border directly above the largest node. The pupil measures 5.5 mm. in its greatest diameter (axis 110 degrees) and is very irregular in outline from numerous broad posterior synechiæ.

The first injection of 1/500 mg. of tuberculin T. R. caused no perceptible change in the temperature and excited no local reaction. Thereon the injections were continued, the temperature being taken every two hours, as follows: October 26: 1/500 mg., maximum temperature (rectal) during the day 99.8 at 11:40 p. m. October 31: 12/500 mg. at 6 p. m., maximum temperature, 99.2; 24 hours after the injection the temperature was 100.6; 6 hours later, 100.6. During the morning the ciliary injection, especially that just below the iris nodes, increased markedly. Vessels now stood out prominently



considered conclusive.) November 11: The patient left the hospital to report at the office for further treatment.

From Nov. 12, 1904, to May 1, 1905, he continued to receive injections *with no untoward* effects on the temperature or local conditions. Up to the middle of April a withdrawal of the atropin would cause an immediate increase in the ciliary injection. From this time on one drop a day only was required. Two further attempts were made to secure a tuberculin temperature reaction, and by the use of the old and not the new tuberculin (T. R.), viz.: First attempt Nov. 15, 1904; temperature, 99 at 12 m.; 4 mg. of the old tuberculin injected: *about ten hours later* the patient experienced a marked chill and his temperature rose to 101.6. (Temperature reaction considered conclusive).

Second attempt, December 16: Temperature 99, at 10 a.m. Injection of 5 mg. of the old tuberculin; 8 hours later there was a maximum temperature of 102, followed two and one-half hours later by a chill. Soreness of joints, jaundice and poor appetite persisted *for two weeks.* (Temperature reaction was considered conclusive.)

March 5, 1905: Under the six months' treatment by tuberculin injections and atropin there has been a steady and gradual improvement in the condition of the eye; e. g., *all the nodes have entirely disappeared, the iris has regained* nearly the color of its fellow, there is no ciliary injection whatever and close work does not redden the eye in the least; vision has improved from 20/70 to 20/30; he has gained 3 pounds in weight and feels quite well, although the afternoon *rise in temperature still continues. The appearance* of the eye is very accurately represented in Fig. 2.

July 1, 1905: *Conditions unchanged; no evidence of the nodes.*

Sept. 8, 1905: Eye quiet. Weight, 125 pound, a gain of *eight pounds. No temperature for two months past.*

SUMMARY OF THE DIAGNOSTIC AND THERAPEUTIC USE OF TUBERCULIN IN THIS CASE.

We had here, then, a plastic iritis eventuating in the formation of definite nodules. Such nodules may occur in a number of affections, some of which may be excluded at once, as leukemia and pseudoleukemia, by the blood count, and glioma, by the age of the patient. Furthermore, there is no history or evidence of a hair or other foreign body penetrating the eye and causing an iritis nodosa (Saemisch). Syphilis can be excluded with a fair degree of probability by the failure of the potassium iodid and mercury to effect an improvement, and, lastly, *leucosarcoma* can be eliminated by the markedly inflammatory nature of the affection. Iris nodes caused by other micro-organisms than the tubercle bacillus have been studied experimentally by Sattler[2] and by Stock,[3] but have not been proved to occur in man. While, therefore, the diagnosis of iritis tuberculosa may rightly be made by exclusion, it is further and finally established as we think:

(1) By the positive general reaction to tuberculin, as shown in the typical sudden rise and fall of the temperature on two separate occasions, and amounting to 2 and 2.5 degrees respectively (allowing for the daily afternoon rise), accompanied by marked chills, pains in the joints, etc. (2) By the repeated local reaction in the eye when the dose of tuberculin injected had reached the physiologic limit of about 1 mg., manifested by a marked increase in the ciliary injection, in the tumefaction and vascularity of the iris nodes. (3) By the persistent afternoon rise of temperature, enlarged supraclavicular glands and slight cough, pointing to a focus of tuberculosis elsewhere, to which that of the eye is probably secondary.

REVIEW OF THE LITERATURE ON THE USE OF TUBERCULIN IN THE EYE.

Following the publication of Koch's method in 1890, Henoch[4] *reported* that he had obtained a marked local and general reaction from tuberculin in a quiet phthisical eye which had been blind for years following a perforating keratitis, and Koehler and Westphal[5] reported that they had seen a 4x2 mm. peripheral corneal ulcer develop in a normal eye, with *profound general reaction,* four days subsequent to a single injection of 1/100 mg. of Koch's lymph.

The next year witnessed the publication of a large number of observations on the use of tuberculin, both for diagnostic and therapeutic purposes, as follows:

Albrand[6] reported tuberculous nodes of the palpebral conjunctiva, with positive inoculation experiments and bacilli findings, absorbed in three weeks by injections of 1/1000 to 3 *mg.;* quiescent 10 months later.

Belliard[7] states that Sulzer obtained a marked local and general reaction in three cases of strumous keratitis with aggravation of the disease.

Bongartz[8] reported two cases of iridocyclitis tuberculosa, with bacilli; no reaction from 3 injections of 1/1000 *mg.;* one eye underwent phthisis bulbi and eye had to be enucleated.

Cohn[9] (1) No local reaction or improvement, though general reaction in a bilateral dacryocystitis; used three injections of .75 to 1 mg. (2) Same results in two cases of phlyctenular keratitis, with interstitial keratitis.

Enslin[10] reported a case of lupus conjunctivæ, corroborated by Cohnheim's experiment: temporary improvement took place, with recurrence and excision. He used large doses.

Gepner[11] reported extensive bilateral lupus conjunctivæ, with ulceration, healed by two injections of 1/1000 mg.

Gradle[12] reported three cases: (1) Interstitial ulcerative keratitis, with perforation, influenced by three weeks' injection (0.15 to 0.3 mg.) with marked local and general reaction. (2) Deep progressive central corneal ulcer healed in 12 days by two injections (0.2 and 0.3 mg.) (3) Shallow progressive central ulcer of each eye entirely healed on two occasions in 11 and 15 days and by 0.2 and 0.5 mg. injections, respectively.

v. Hippel[13] reported two cases: (1) Obstinate inflammation of each cornea and lids, remarkably improved by one injection of *1/200 mg. in ten days.* (2) Eczematous corneal *disease of each eye healed* by two injections (1/200 and 3/1000 mg.), with marked general reaction.

Koenigshoefer and Maschke[14] reported nine cases: (1) Keratitis interstitialis; clearing of opacities in six days by two injections of ½ mg., with local and general diagnostic reaction. (2) Eczematous corneal ulcer; rapid healing following one injection of ½ mg. (3) Ulcer (4 by 3 mm.) healed in 4 days by ½ mg. injection, with local and general reaction. (4) Ulcer of 2 mm. nearly healed in 5 days, with clavicle. (b) Leucopenia—only 3,500 whites—8 per cent. of them small mononuclear and 32 per cent. large mononuclear (i. e., 'relative' lymphocytosis). (c) A little cough without expectoration or discoverable pulmonary localization. Suggests involvement of the mediastinal glands. (d) No bacilli found in urine. Findings suggest glandular tuberculosis.

Six subsequent examinations of the sputum for tubercle bacilli were negative.

Treatment.—Commencing Sept. 7, 1904, potassium iodid and later mercurial inunctions were used for several weeks. The two nodes not only steadily increased in size and became grayish-opaque, but three additional nodes appeared in the lower nasal quadrant, ciliary injection became more marked and fine precipitates developed over the lower half of the posterior surface of the cornea. These precipitates were not arranged in the classical triangular shape characteristic of serous cyclitis but were spread over the entire lower segment without particular form and indicated rather an extension of the inflammation from the iris below onto the adjacent cornea.

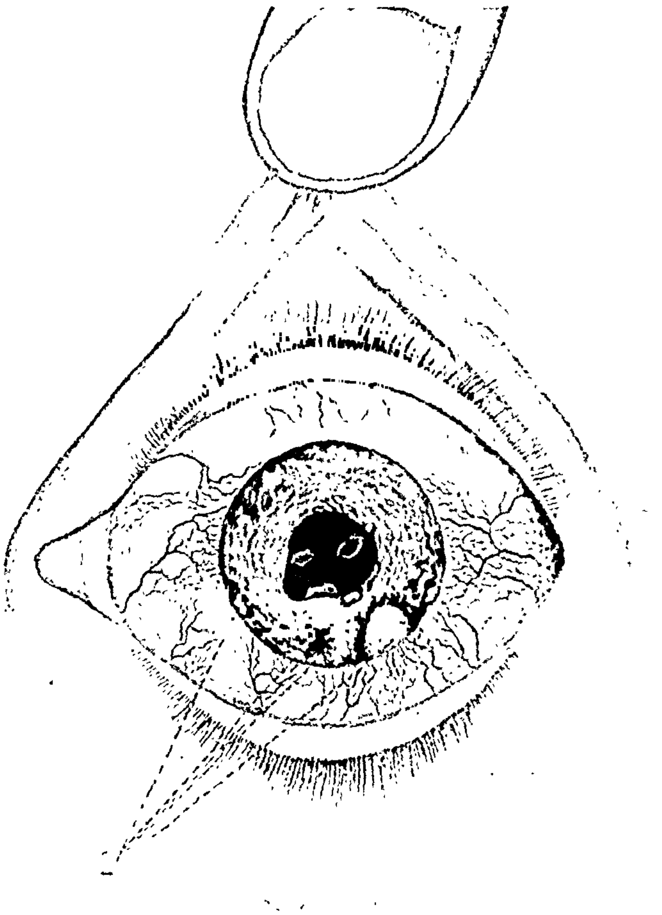

Fig. 1.—Active Iritis Tuberculosa. 1, nodes.

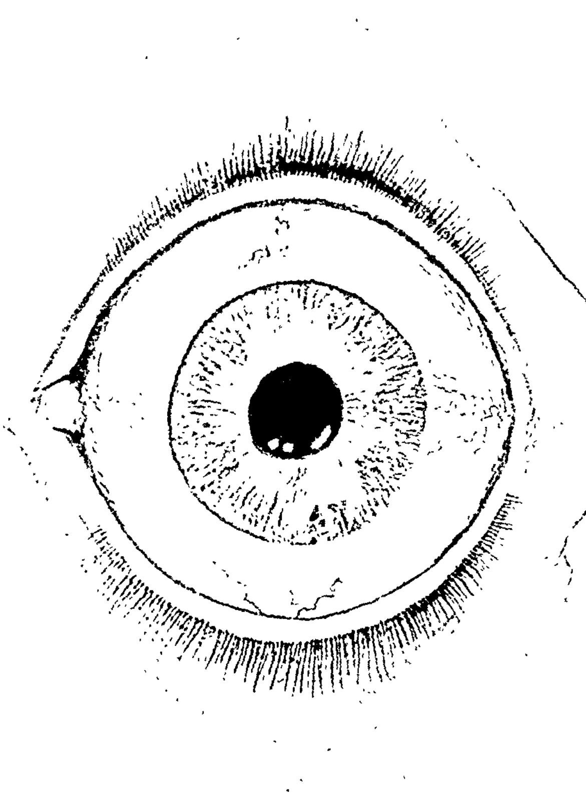

Fig. 2.—Healed Iritis Tuberculosa.

Diagnosis.—Iritis tuberculosa.

Tuberculin Treatment.—Oct. 24, 1904, at the suggestion of Dr. Brown, the patient was placed in a hospital and given injections of Koch's new tuberculin T. R., with the instillation of atropin, as advocated by E. v. Hippel (1904). At this time a drawing of the eye was made (Fig. 1) and notes on the condition of the eye as follows:

On focal and transmitted lights one finds: (1) Nearly complete circum-corneal injection; (2) that the posterior surface of the cornea, especially the lower half, is dotted by pinhead sized, thin, yellowish-white masses; (3) that a deep, smooth, vascularized, light-yellow, translucent, pad-like, lens-shaped node, with flattened anterior surface and sharply convex border is attached by a small, constricted base well down toward the very angle of the iris root beneath the opaque corneo-scleral limbus as if springing from the ligamentum pectinatum. The node lies at the lower end of a line drawn through axis 110 degrees, and measures 2.5 mm. in the vertical plane, 2 mm. in the horizontal and 2 mm. in the antero-posterior plane. At least its superior one-half rides free over the iris and obscures four-sevenths of the iris surface measured from the root toward the pupillary border. Four smaller nodes about the size of pinheads are seen, two of them seated in the sinus angle below, one nasal, and the fourth at the pupillary border directly above the largest node. The pupil measures 5.5 mm. in its greatest diameter (axis 110 degrees) and is very irregular in outline from numerous broad posterior synechiæ.

The first injection of 1/500 mg. of tuberculin T. R. caused no perceptible change in the temperature and excited no local reaction. Thereon the injections were continued, the temperature being taken every two hours, as follows: October 26: 1/500 mg., maximum temperature (rectal) during the day 99.8 at 11:40 p. m. October 31: 12/500 mg. at 6 p. m., maximum temperature, 99.2; 24 hours after the injection the temperature was *100.6; 6 hours later, 100.6. During the morning* the ciliary injection, especially that just below the iris nodes, increased markedly. Vessels now stood out prominently over the surface of the largest node and the patient complained of tenderness of the eye on pressure. This local reaction lasted about 12 hours and then abruptly disappeared. November 2: maximum temperature, 99.7; no injection. November 3: maximum temperature, 99.6; no injection. November 4: maximum temperature, 99.6; no injection. November 5, 10/500 mg. at 6 p. m.; no change in the temperature or in the local condition. Injection of 10/500 mg. of tuberculin T. R. at 6 p. m. Twenty-four hours later ciliary injection was again increased and completely encircled the cornea; the large node was deeply congested and of a brick-red color, remaining so for several hours. The maximum temperature (8 p. m.) was 99.8. November 7: 6:40 p. m., temperature, 98.4. Injected 4 mg. of tuberculin T. R. for the purpose of obtaining a diagnostic reaction. November 8: maximum temperature, 4 p. m., of 100, lasting one hour. The large node especially was more hyperemic and the ciliary injection increased. (Reaction not considered conclusive.) November 11: The patient left the hospital to report at the office for further treatment.

From Nov. 12, 1904, to May 1, 1905, he continued to receive injections with no untoward effects on the temperature or local conditions. Up to the middle of April a withdrawal of the atropin would cause an immediate increase in the ciliary injection. From this time on one drop a day only was required. Two further attempts were made to secure a tuberculin temperature reaction, and by the use of the old and not the new tuberculin (T. R.), viz.: First attempt Nov. 15, 1904; temperature, 99 at 12 m.; 4 mg. of the old tuberculin injected: about ten hours later the patient experienced a marked chill and his temperature rose to 101.6. (Temperature reaction considered conclusive).

Second attempt, December 16: Temperature 99, at 10 a.m. Injection of 5 mg. of the old tuberculin; 8 hours later there was a maximum temperature of 102, followed two and one-half hours later by a chill. Soreness of joints, jaundice and poor appetite persisted for two weeks. (Temperature reaction was considered conclusive.)

March 5, 1905: Under the six months' treatment by tuberculin injections and atropin there has been a steady and gradual improvement in the condition of the eye; e. g., all the nodes have entirely disappeared, the iris has regained nearly the color of its fellow, there is no ciliary injection whatever and close work does not redden the eye in the least; vision has improved from 20/70 to 20/30; he has gained 3 pounds in weight and feels quite well, although the afternoon rise in temperature still continues. The appearance of the eye is very accurately represented in Fig. 2.

July 1, 1905: Conditions unchanged; no evidence of the nodes.

Sept. 8, 1905: Eye quiet. Weight, 125 pound, a gain of eight pounds. No temperature for two months past.

SUMMARY OF THE DIAGNOSTIC AND THERAPEUTIC USE OF TUBERCULIN IN THIS CASE.

We had here, then, a plastic iritis eventuating in the formation of definite nodules. Such nodules may occur in a number of affections, some of which may be excluded at once, as leukemia and pseudoleukemia, by the blood count, and glioma, by the age of the patient. Furthermore, there is no history or evidence of a hair or other foreign body penetrating the eye and causing an iritis nodosa (Saemisch). Syphilis can be excluded with a fair degree of probability by the failure of the potassium iodid and mercury to effect an improvement, and, lastly, leucosarcóma can be eliminated by the markedly inflammatory nature of the affection. Iris nodes caused by other micro-organisms than the tubercle bacillus have been studied experimentally by Sattler[2] and by Stock,[3] but have not been proved to occur in man. While, therefore, the diagnosis of iritis tuberculosa may rightly be made by exclusion, it is further and finally established as we think:

(1) By the positive general reaction to tuberculin, as shown in the typical sudden rise and fall of the temperature on two separate occasions, and amounting to 2 and 2.5 degrees respectively (allowing for the daily afternoon rise), accompanied by marked chills, pains in the joints, etc. (2) By the repeated local reaction in the eye when the dose of tuberculin injected had reached the physiologic limit of about 1 mg., manifested by a marked increase in the ciliary injection, in the tumefaction and vascularity of the iris nodes. (3) By the persistent afternoon rise of temperature, enlarged supraclavicular glands and slight cough, pointing to a focus of tuberculosis elsewhere, to which that of the eye is probably secondary.

REVIEW OF THE LITERATURE ON THE USE OF TUBERCULIN IN THE EYE.

Following the publication of Koch's method in 1890, **Henoch**[4] reported that he had obtained a marked local and general reaction from tuberculin in a quiet phthisical eye which had been blind for years following a perforating keratitis, and **Koehler** and **Westphal**[5] reported that they had seen a 4x2 mm. peripheral corneal ulcer develop in a normal eye, with profound general reaction, four days subsequent to a single injection of 1/100 mg. of Koch's lymph.

The next year witnessed the publication of a large number of observations on the use of tuberculin, both for diagnostic and therapeutic purposes, as follows:

Albrand[6] reported tuberculous nodes of the palpebral conjunctiva, with positive inoculation experiments and bacilli findings, absorbed in three weeks by injections of 1/1000 to 3 mg.; quiescent 10 months later.

Belliard[7] states that Sulzer obtained a marked local and general reaction in three cases of strumous keratitis with aggravation of the disease.

Bongartz[8] reported two cases of iridocyclitis tuberculosa, with bacilli; no reaction from 3 injections of 1/1000 mg.; one eye underwent phthisis bulbi and eye had to be enucleated.

Cohn[9] (1) No local reaction or improvement, though general reaction in a bilateral dacryocystitis; used three injections of .75 to 1 mg. (2) Same results in two cases of phlyctenular keratitis, with interstitial keratitis.

Enslin[10] reported a case of lupus conjunctivæ, corroborated by Cohnheim's experiment: temporary improvement took place, with recurrence and excision. He used large doses.

Gepner[11] reported extensive bilateral lupus conjunctivæ, with ulceration, healed by two injections of 1/1000 mg.

Gradle[12] reported three cases: (1) Interstitial ulcerative keratitis, with perforation, influenced by three weeks' injection (0.15 to 0.3 mg.) with marked local and general reaction. (2) Deep progressive central corneal ulcer healed in 12 days by two injections (0.2 and 0.3 mg.) (3) Shallow progressive central ulcer of each eye entirely healed on two occasions in 11 and 15 days and by 0.2 and 0.5 mg. injections, respectively.

v. Hippel[13] reported two cases: (1) Obstinate inflammation of each cornea and lids, remarkably improved by one injection of 1/200 mg. in ten days. (2) Eczematous corneal disease of each eye healed by two injections (1/200 and 3/1000 mg.), with marked general reaction.

Koenigshoefer and **Maschke**[14] reported nine cases: (1) Keratitis interstitialis; clearing of opacities in six days by two injections of ½ mg., with local and general diagnostic reaction. (2) Eczematous corneal ulcer; rapid healing following one injection of ½ mg. (3) Ulcer (4 by 3 mm.) healed in 4 days by ½ mg. injection, with local and general reaction. (4) Ulcer of 2 mm. nearly healed in 5 days, with local and general reaction. (5) Ulcers of 2 mm. and less healed in 2 days by ½ mg., with local and general reaction. (6) Large ulcer healed in 6 days by two injections of ½ mg., with local and general reaction. (7) Iris nodes almost entirely absorbed in 10 days by three injections of ½ to 1 mg. (8) Large nodes on lid margins of each eye absorbed in five days by two injections of ½ and 1 mg.; temperature reaction only. (9) Small tumor of tarsal conjunctiva absorbed in 7 days by two injections of ½ and 1 mg., with local and general reaction.

Landgraf[15] reported a case of granuloma tuberculosum filling one-half of anterior chamber and invading the ciliary body, reduced to a minimum by 24 almost daily injections of 1/1000 to 1/500 mg., with local and general reaction.

Leber[16] reported a case of nodes over the whole iris resorbed without a trace in 7 weeks by 10 injections of 1/1000 to 8/1000 mg. extending over but 4 weeks; local and general reaction.

Mikulicz[17] reported fresh phlyctenule caused by tuberculin injections for a tubercular elbow joint.

Pflueger[18] reported conjunctival tuberculosis, with local and general reaction on each of 12 injections (1/500 to a few mg.), with increase in the size of the tubercular areas.

Sattler[19] reported three cases: (1) Tuberculous nodes and ulcer of palpebral conjunctiva, corroborated by Cohnheim's experiment, permanently healed by 15 injections of 1/200 to ¼ mg. (2) Trachoma-follicle-like fornix tubercular nodes, corroborated by Cohnheim's experiment, healed by 10 injections of 1 to 10 mg. (3) Lupus conjunctivæ, corroborated by Cohnheim's experiment, without definite results in the time treated.

Schaffraner[20] reported a case of lid and corneal disease entirely relieved by 4 injections of 1/1000 to 8/1000 mg. in 4 weeks, with local and general reaction.

Schwann[21] reported an almost lens-sized corneal ulcer healed in 15 days by 6 injections of 1/1000 to 7/1000 mg., with local and general reaction.

Schweigger[22] reported three cases: (1) Caries and abscess of the lower orbital margin healed completely in 2 weeks by 3 injections of 1.5 to 4 mg., with local and general reaction. (2) Corneal infiltration and eczema much improved by 2 injections of 2 and 5 mg. in ten days, but with no decided local or general reaction. (3) Lachrymal disease, with no reaction or improvement on 7 injections of 1 to 10 mg. (4) Blennorrhea of the sac, with possible bone disease, without local reaction or improvement, though general reaction on 2 injections of 5 mg. each.

Silex[23] reported lupus of face and lids somewhat improved at first by the injections, but much worse later, and somewhat improved finally by other treatment; 120 mg. in all were used.

Uhthoff[24] used 1/5000 to 1/1000 mg. injections in 10 cases of phlyctenulæ, keratitis superficialis vascularis, keratitis fassicularis, corneal ulcer, etc., with general reaction in all, but local reaction in only 3, and a generally favorable and prompt result in the treatment.

Wagner[25] reported four cases: (1) Three cases of lupus of the lid skin, with fistulous dacryocystitis, healed by 25 injections of 1/200 to 30 mg., with local and general reaction in each. (2) Tuberculous ulcer of palpebral conjunctiva, cured in 4 weeks by 2 injections of 1/1000 to 1/500 mg., with temperature reaction. (3) Node-form tubercular scleritis cured in 6 weeks by injections of 1/200 mg., increased by 3 mg. each dose, with local and general reaction. (4) Tubercular iris nodes reduced to a minimum by injections of 7/1000 to 1/10, with local and general reaction.

Subsequent to 1891 we find the following reports:

Haase[26] reported a case of iridocyclitis tuberculosa, with general but no local reaction on 9 injections of 1 to 4 mg. extending over 2 months; though the nodes disappeared two months later, the author thinks it was not due to the tuberculin.

Kunz[27] recommends the use of tuberculin for diagnostic purposes.

Zimmermann[28] reported the case of a patient with severe tuberculosis of the eye, confirmed by a histologic examination, cured by injections of 1/500 mg.; the fellow eye had been removed five years before.

Gradle[29] used tuberculin in 4 cases of interstitial keratitis, with positive febrile reaction in all.

Reimar[30] reported that two months' use of tuberculin (6/10000 to 1 mg.) had no essential local or general effect or curative action in a case of tuberculosis of the conjunctiva with bacilli on histologic examination and with positive inoculation experiments.

Schieck[31] studied the subject very carefully and reported 5 cases, with a general favorable result, as follows: (1) A large iris node disappearing under injections of 1/10 to 5 mg. of the old tuberculin during 6 months, with recurrence and resorption, and a second recurrence and resorption by 1/500 to 4 mg. of the new tuberculin T. R., with final quiescence of 2 months; temperature reaction. (2) Iris angle nodes disappearing on 2 injections of 1/5 to ½ mg., with extensive recurrence over 2/3 of iris and resorption in 5 months by 1/20 to 5 mg. and even 18 mg., without essential local or general reaction; second recurrence over two-thirds of iris and final resorption after 2 months of ½ to 5 mg., and nine and one-half years of quiescence (v. Hippel). (3) Iritis plastica treated 5 weeks by ½ to 1 mg. injections, without local or general reaction or improvement, but with the development of lupus nodes; all were later cured in 4 weeks under expectant treatment. (4) Iris node in each eye with development of a hypopyon under 1/200 to 7/10 mg. injections extending over 3 weeks and subsequent absorption of hypopyon and nodes under expectant treatment, with 2 years of quiescence. (5) Iris and corneal nodes entirely absorbed under 24 injections of 1/500 to 1 mg. in three months, with no local or general reaction; 5 years of quiescence.

Uhthoff[32] contributed a notable case of conjunctival tuberculosis, in which the nodes excised gave a positive experimental tuberculosis in a rabbit and tubercle bacilli were found on anatomic study, yet a careful tuberculin test with 2 injections of 1/10 and 0.000375 mg., respectively, gave no local reaction, though some temperature reaction. The disease was not influenced.

32. Uhthoff: (1900) "Bemerkungen zur Scrophulose und Tuberculose nebst einem Beitrag zur Tuberculose der Conjunctiva." Berl. klin Woch., No. 50, N. 1144-1148.

Morax and Chaillous[33] reported three cases: (1) Tuberculous nodes over one-half of the cornea and on the lids of each eye absorbed in two weeks after an injection of tuberculin, with a local and general reaction. (2) Iris nodes absorbed in six weeks after one injection of 1/20 mg., accompanied by both local and general reaction. (3) Nodes in the cornea absorbed on one injection of 1/20 mg. and the use of mercury and potassium iodid.

Falckenberg[34] reported cases of iris and choroidal, as well as probable bone tuberculosis. No improvement after one month of 1/500 to 1/50 mg. injections, though there was both local and general reaction, and inoculation experiments were positive. The eye was enucleated following a spontaneous perforation, and the patient died one month later from meningitis. (2) Iritis tuberculosa, with no improvement or local or general reaction on 10 injections of 1/500 to 1/20 mg. during 18 days, and enucleation followed by death one month later from meningitis. No bacilli were found, though inoculation experiments were positive. Falckenberg says he thinks the doses were not sufficiently large or numerous.

Haab[35] used tuberculin for diagnostic purposes in many cases in which the diagnosis was not clear, among them two cases of iritis tuberculosa, with marked local reaction in the nodes, as well as the febrile reaction.

Enslin[36] obtained a typical tuberculin temperature reaction in 8 cases of keratitis parenchymatosa, and with local reaction in some of them by 1/10 to 3 mg. injections; also in a case of conjunctival tuberculosis and in a case of iris tuberculosis.

Handmann[37] reported two cases: (1) Iris angle nodes reduced to 1/2 or 2/3 by 9 weeks of injections of 1/1000 to 3 mg., and completely absorbed one and one-half years later. (2) Iris nodes in each eye absorbed with scarcely a trace left after 10 weeks of 1/100 to 2 mg. Local and general reaction.

Krueckmann[38] considers the diagnostic value of tuberculin to be very great in doubtful cases.

v. Michel[39] saw small nodes appear on the iris and sclera a few hours after an injection of tuberculin in iritis.

Petella[40] used tuberculin T. R. for diagnostic and partly for therapeutic purposes in two cases, one of conjunctival tuberculosis, and recommends it as the most certain diagnostic means.

Pflueger[41] has used tuberculin for diagnostic purposes for the past two years with the most satisfactory results. He considers its diagnostic reaction to be of great weight in doubtful cases.

Salie[42] reported three cases: (1) Tubercular tarsal-conjunctival excrescences absorbed in 7 weeks by 10 injections of 1/500 to 6/500 mg. with slight local and general reaction; recurrence with a 4x1 mm. ulcer the following year, again healed by injections. (2) Tarsal conjunctival excrescences and ulceration healed by 25 injections of 1/500 to 21/550 mg. in three months. Inoculation experiments were positive. (3) Tubercular granulations and ulcer of the tarsal conjunctiva *slowly healed* by 61 injections of 1/500 to 21/50 mg., along with 5 cauterizations extending over 4 months. Inoculation *experiments* were positive.

Darier[43] reported a case of interstitial keratitis treated with good results; the cornea cleared after a number of injections. There were marked local reactions.

Enslin[44] used tuberculin as a differential diagnostic means between lues and tuberculosis in 24 cases of keratitis parenchymatosa; five gave the typical local and general reaction.

Haab[45] used tuberculin for diagnostic purposes with positive results in suspected tuberculosis of the conjunctiva 2; of the lachrymal gland 1; in severe corneal eczema 1; iritis with and without definite nodes 9; conglomerate tubercle of the choroidea 1; choroiditis 3;; neuroretinitis 2; choked disc 2. He obtained the local diagnostic reaction in each case. He saw improvement from tuberculin therapy in uveal tuberculosis a nodular tubercular iridochoroiditis entirely cured by 14 injections, and a choroiditis with striking local reaction, though no curative results, on 4 injections.

Morinami[46] reported that Kayser says he obtained a local and general reaction in three cases of a chronic type by the use of 1 to 3 mg. of tuberculin.

Weigelt[47] reports a large iris tubercle markedly reduced in size by 4 weeks' treatment by new tuberculin, although several smaller nodes appeared in other parts of the iris.

Dupuy-Dutemps[48] reported that the results of tuberculin are sometimes unsatisfactory.

Groenouw[49] speaks at length of the diagnostic and therapeutic use of tuberculin.

Hess[50] has treated 9 cases of iritis tuberculosa with tuberculin T. R. with a favorable result in all, and an unfavorable result in none. He says tuberculin should find more extended systematic use as a diagnostic means.

v. Hippel[51] reported ten cases: (1) Iris nodes each eye absorbed by 26 injections of 1/500 to 1/12 mg. in two months; recurrence 4½ years later with perforation of the cornea; nodes absorbed after 33 injections, though phthisis bulbi was inevitable in one eye. (2) Iris nodes absorbed in 7 weeks by 23 injections of 1/500 to 1 mg., with 4 years quiescence. (3) Iris nodes absorbed by 56 injections of 1/500 to 1/50 mg. in 4½ months, with 2 years of quiescence. Histologic corroboration later by Schmidt-Rimpler. (4) Severe corneal and iris tuberculosis with nodes absorbed by 36 injections of 5/500 to 6/50 mg. in 3 months. (5) Iris nodes disappeared on 69 injections of 1/500 to 9/50 mg. in 1 month. (6) Primary tuberculosis of ciliary bodies; iris nodes absorbed and cyclitis completely cured by 68 injections of 1/500 to 40/50 mg. in 5 months. (7-9) Three cases of severe conjunctival tuberculosis permanently healed by tuberculin without lid malposition, after resisting 6 months of other treatment. (10) Severe scleral tuberculosis and corneal nodes absorbed by 1/500 to 1/5 mg. Recurrence and cure after more injections, with 6 months' quiescence.

v. Michel[52] remarked that he had seen very severe local and general reaction in iritis tuberculosis after tuberculin injections. A severe pneumonia followed an injection in disease of the lachrymal sac. The persons affected were not especially weak persons. He warns against the therapeutic use of tuberculin, and says it is preferably used for diagnostic purposes.

Moissonnier[53] recommends the diagnostic use of tuberculin in doubtful cases.

Puccioni[54] reported that tuberculosis, especially when localized in the anterior chambers, *reacted to tuberculin.* Later anatomic examinations demonstrated the tubercular nature of the disease.

Schoeler[55] used tuberculin methodically to determine the diagnosis in 48 cases, including scleritis, iritis serosa, keratitis parenchymatosa and choroiditis disseminata. He very strongly advised the use of the drug along with and in preference to other means of diagnosis.

Use of Tuberculin in Ophthalmology.

The small numbers after the author's names refer to case numbers in their reports.

Stanculeano[56] reported eight cases: (1) Corneal infiltrate markedly improved on 10 injections of 1-5 mg. in 8 weeks. Local and general reaction. (2) Similar cases (6 injections during 7 weeks). (3) Keratitis and iritis with improvement by 1 injection of 1-5 *mg., extending* over 11 weeks. Local and general reaction. (4) Keratitis and iritis improved by 6 injections of 1-5 mg. during 4 weeks. General, but no *local reaction.* (5) Keratitis, with slight iritis, with general but no *local reaction* to 4 injections of 1-5 mg. (6-8) No local reaction, though *reaction on* 1 and 2 injections of 1/10 to 2 mg.

Kayser[57] gives an extended review of recent diagnostic and therapeutic measures employed in tuberculosis of the eye, including the use of tuberculin.

Wehrli[58]: *A case of lupus cornea, with a certain reaction* (temperature of 100.4 degrees).

Reunert[59]: *Tuberculous iris nodes completely absorbed in* 7 weeks by 6 *months* of injections (1/500 to 1 mg.), given every other day, with 4 *months of* subsequent quiescence. (v. *Hippel.*)

The *accompanying* table comprises a summary of the case reported.

CONCLUSIONS.

There is very little question as to the value and reliability of tuberculin as a diagnostic agent. Failure to obtain the reaction on one injection, however, is not conclusive, and, according to Tinker,[60] successive doses of 3, 6 and even 9 mg. should be used before tuberculosis be considered definitely excluded. *Our own experience,* however, although *confined* to but one case, would lead us to recommend that the very lowest possible dose be used in view of the profound general reaction which we have seen with a 5 mg. injection. The early view that its use caused a dissemination of the tuberculous material throughout the body has been very much modified in recent years.

Tinker has used it for general diagnostic purposes in over 400 surgical cases, with no untoward results that could be directly attributed to its use. He notes that Virchow's objections were very cautiously expressed and only once, and were based on 21 postmortems made during the first year of the use of tuberculin when very large doses were employed. Even at that time, however, his views were opposed by Ziemssen, Gultmann and Ehrlich, Schede, Curschmann and others. As to its therapeutic value, less may rightly be said, since far too few conclusive cases have as yet been studied, the present case being but the thirty-third detailed report *in the literature.* Much tuberculous disease of the eye is of a chronic, non-virulent type, with sparse bacilli *findings* and a more or less pronounced tendency to spontaneous healing, as first pointed out by Leber[16] (1891). Such patients can certainly be helped by tuberculin, and the series of cases contributed by Schieck[31] and v. Hippel[12] in particular show that very advanced tuberculosis can be arrested, improved or entirely cured with *years of subsequent immunity.*

Professor v. Hippel closes his article with the statement:

> "On the ground of the facts which I have contributed I consider it indicated that we possess in tuberculin T. R. a means which, if rightly used, will permanently heal the severest tuberculosis of the eye."

DISCUSSION.

Dr. Albert E. Bulson, Jr., Fort Wayne, Ind., said that he had a similar case of tuberculous iritis under tuberculin treatment at the time, and that he had the pleasure of seeing Dr. Brown's case when it was presented before the Chicago Ophthalmological Society for diagnosis, and at the time suggested the use of tuberculin to establish a diagnosis. He believes that ophthalmologists are apt to be led into error as to the value of tuberculin in establishing a diagnosis unless certain well-defined rules are followed in its use. Dr. Bulson said that while Dr. Brown speaks of using small doses for diagnostic purposes and increasing the dose if no reaction is secured, he is inclined to agree with many observers that a large dose, say from 10 to 12 milligrams, is warranted as an initial diagnostic dose, and if no reaction is secured the dose may be repeated in the course of a few days. Even in the presence of a localized tuberculous infection a small dose of tuberculin may produce absolutely no reaction. It is of the most importance that a record of the temperature for three days prior to the injection be carefully kept for comparison with the record following the injection, as some of these patients having only a localized area of tuberculous infection, as in the iris, will show very little reaction, even with a large dose of tuberculin. On the other hand, a decided reaction should not be accepted as a positive indication that the patient has tuberculosis, for the rise in temperature may be only coincident, as Dr. Bulson has known it to be on two occasions in the practice of one of his confrères. The injections should be sufficiently large and continued over a sufficient period of time definitely to establish the fact that a reaction is or is not being produced by the injections. Syphilis should be excluded, as it has been known to influence reaction from tuberculin injections. The case of tuberculous iritis in a 4-year-old child which Dr. Bulson has under tuberculin treatment at the present time, exhibited a marked reaction on several occasions to injections of 10 milligrams, but has failed to show reaction to doses of half that size. With each injection the eye, which has lost light perception, but gives the patient no discomfort, assumes an angry red appearance, and the seven nodules on the iris become infiltrated and swollen. This local reaction in the eye lasts from twelve to thirty-six hours, leaving the eye about as it was before the injection. Treatment has been carried on regularly for about six weeks, and though the general physical appearance of the patient has improved, the condition of the eye seems to be unchanged. As a means of establishing a diagnosis of tuberculous iritis, the injection of tuberculin is certainly warranted, but as nearly as Dr. Bulson can learn by reference to the literature on the subject, the curative value of tuberculin in these cases depends largely on whether the lesion is localized and on its degree of advancement.

Dr. E. V. L. Brown, Chicago, said that the absolute diagnostic value of tuberculin for tuberculosis, and tuberculosis only, is now very generally accepted. The syphilographers are united on this point. The article by Tinker in *Johns Hopkins Hospital Reports* is very conclusive, and Dr. Brown thinks, can be relied on as being absolutely diagnostic. In reply to a question, he said that the use of air in the anterior chamber in these cases was reviewed by Kaiser recently in the *Klin. Monatsbl. f. Augenheilkunde.*

PNEUMONIA IN THE YOUNG.*

EDWARD F. WELLS, M.D.
Professor of Clinical Medicine and Associate Professor of Practice of Medicine in the College of Medicine of the University of Illinois; Physician to Cook County Hospital.
CHICAGO.

Pneumonia is always interesting. In the young, interest is heightened by the statistics and statistical fallacies of its prevalence; by important problems connected with its causation and avenues of bacterial invasion, by modifications in its morbid anatomy and symptomatology, by the frequency of serious complications, by the apparent difficulties of diagnosis, by the uncertainties of prognosis, and by the chaotic state in which we find the literature of its management.

To estimate fairly the prevalence and fatality of pneumonia in the young is a statistical and judicial feat of no mean proportions. In tabulating and analyzing 30,025 cases of, and 225,642 deaths from pneumonia, the following conclusions may be drawn: During early childhood pneumonia is encountered oftener than at any other period; from 10 to 30 years, much less

* Read in the Section on Diseases of Children of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

frequently; from 30 to 50, somewhat oftener; subsequently with diminishing frequency. On the contrary, if its prevalence is estimated by comparing the deaths caused by pneumonia with the number of persons living at various age periods it will be found that in early childhood its mortality prevalence is moderate; from 10 to 20 years, it sinks to its lowest level; from 20 to 50, it gradually but moderately advances; beyond this it rises with great rapidity, and is greatest in old age. These facts are clearly shown in the accompanying table.

The apparent inconsistencies shown by these tables may be explainable by a broad survey of the concomitant facts in the case; as, e. g., patients of different age periods do not seek admission to hospitals in equal proportions; consulting physicians do not see patients of various ages in fair proportion; the death rate varies at various periods, etc.

Children of any age may have pneumonia, but the recently-born infant is least liable to be affected; the liability increasing up to a certain illy defined period, to subsequently decline somewhat. The reason for this I shall endeavor to give later.

It is proper for me to state at this time that I acknowledge the infrequent occurrence of pulmonary inflammations from various bacteria, but pneumonia is due only to the pneumococcus. In this connection some pertinent facts pertaining to this germ require consideration: The pneumococcus is present in the upper respiratory passages of a very large proportion—probably 50 per cent.—of healthy persons. It is disseminated by being thrown into the air by coughing and sneezing and by the dust from dried and pulverized contaminated sputum from infected, but not necessarily pneumonic, individuals. As long as the pneumococcus remains in this locality it is usually innocent. If, however, it finds its way into the pulmonary alveoli pneumonia will probably result; if it finds its way into the blood and grows, pneumococcemia follows. The pneumococcus is present in the blood in probably all cases of pneumonia. A child born of a pneumonic mother may be pneumococcemic, and may quickly become pneumonic. I have examined the throat secretions of several recently born infants, but have always found them free from pneumococci. Later when these germs find lodgment in the throat, nostrils, etc., they remain persistently, if not permanently. For example, in several hundred examinations, I have not failed to find the pneumococcus in every person who has once had pneumonia, no matter how long the period since the attack.

The child, once the throat becomes infected with the pneumococcus, is in constant danger of an attack of pneumonia. From this it is protected by the integrity of the sensitive and alert respiratory reflexes. Should these barriers fail, as, e. g., in the profound sleep which may follow exhaustion, or exposure to excessive cold, etc., particles of pneumococci-laden throat secretions may be aspirated into the bronchi, to finally lodge in the alveoli, with pneumonia as the result.

When the alveoli have once become infected, severe symptoms promptly follow in the great majority of cases. In the midst of health, or after a few hours of indisposition, the child awakens from sleep, possibly at an unusual hour, with considerable or high fever, often with vomiting, and evidently seriously ill.

The temperature quickly reaches a markedly higher level than is usual in adults; from 103 to 105 F. is the rule; above 105 is very common; rarely is it persistently under 103; irregular temperatures are very frequent. The pulse is rapid, rarely being under 130; usually ranging above 150; sometimes reaching 180 or 200; with exertion it may become almost uncountable. Respiration is increased in frequency, absolutely and especially in proportion to the pulse rate; rarely is it under 50; usually it ranges between 60 and 80; often it rises above 80, and may exceed 100. The normal pulse-respiration rate is reduced to 3:1, 2:1, or less.

Chill, which is so conspicuously the rule in adults, is absent in infants, and is infrequent in young children. Convulsions, of which we read so much, have been comparatively rare in my experience. They may have been more frequent a generation or two ago.

Pain is present and is manifested by indisposition to voluntary, and resentment to passive movements; by crying and featural expressions of pain, especially on being disturbed; by shallow breathing and an evident disposition to avoid nursing, and every exertion of movement which entails deep inspiration; by evidences of suffering on pressure being made on the abdomen or some portion of the chest. Cough is always present. It is usually short and evidently restrained; it is often heard only when the child is moved or fed, when it may be obscured by the cry, resentment and other evidences of accompanying pain; it is often so inconspicuous as to remain unnoticed by the attendants until attention is directed to it by the physician; it may be a very prominent feature. The well-known expiratory grunt is usually present.

The pneumonic infant usually persistently refuses food, and drinks only at long intervals and with evident reluctance. This is probably due to a disinclination to be moved, to the pain and distress caused by the deeper breathing required in nursing, and to anorexia. Gastrointestinal disturbances are the rule. Intestinal distention may accompany a profound benumbing of the reflexes, and when followed by diarrhea is of ominous import. At the height of the attack the urine frequently contains albumin, hyaline and granular casts; sometimes red corpuscles; rarely hemoglobin.

The blood contains pneumococci; the serum becomes gradually more and more heavily laden with toxins, including agglutinins; leucocytosis occurs early in the vast majority of cases and continues well into convalescence, the increase being in the polynuclears.

The physical signs of pneumonia are present and discoverable, at some stage, in practically all cases. They may be late in appearing; extraordinary care and skill may be required for their detection; they may be found in unexpected localities. Diminution in the respiratory sound within a circumscribed area, with crepitation, when the child breathes deeply, as with crying, is usually the first sign to be heard. Crepitant râles may be remarkably distinct and exquisitely typical, or they may be indistinct, moist, soft and decidedly atypical. Bronchial breathing may not be audible, because of the weakened respiration; it may be moist and low-pitched; it may be limited to a small area in the back, even when extensive consolidation is present; it may sometimes be heard far beyond the affected region, even to the opposite lung. Friction sounds are heard infrequently, because of their short duration in many cases and the great care required in their detection. Dullness on light percussion is present whenever the consolidated area is of any considerable size. If percussion should be too forcible the dullness will be obscured, or even tympanitic resonance, as, e. g., from vibrations arising in a distended stomach or intestine may be obtained. In any case the dullness is more accurately described as diminished resonance. In cases with delay in the appearance of physical signs they oftenest first show themselves high up in the axilla, or between the scapula and the spine, and I have been forcibly impressed with the frequency in which they may be detected by careful examination in these localities in cases in which they were supposed to be absent. In my cases the right lung has been oftener affected than the left, although the preponderance has not been as pronounced as in adults. The consolidation is oftener basal than apical. It is usually clearly lobar. Sometimes it takes on a spreading form.

Nervous symptoms are rarely inconspicuous. The child is dull, drowsy and apathetic, but resenting movements and other disturbance. Delirium is rare. Spasmodic twitchings, which cause pain, are frequent. Rigidity of the neck is usually due to otitis media.

Surface pallor is the rule; a natural color is present in some cases; rarely is there a persistent flush of the cheeks; cyanosis, except as a fatal termination is approaching, is uncommon. Various erythemas may be present at some time during the attack. Herpes is infrequent, although I have seen some remarkable examples. Icterus may be present in some rare cases, but it is usually slight and of a dusky hue.

The course, type, severity and danger of an attack of infantile pneumonia will vary in various localities and at different times, depending on the natural or acquired virulence of the strain of infecting pneumococcus. These modifications are so multitudinous as to defy any short analysis.

The duration is somewhat shorter in infants and young children than in adults. Short, evanescent cases are not rare; a duration of somewhat less than a week is the rule; protracted cases may be due to the successive involvement of lobe after lobe, with a moderate interval between, or, and this is oftener the cause of the delay, to an unrecognized, but not unrecognizable, empyema. The attack usually terminates by a rapid decline of all the symptoms, the physical signs continuing longer, the so-called crisis; a gradual and more prolonged ending—lysis—is not rare.

Serious complications are more frequently encountered in pneumonia of the young than in adults. Of these empyema is the chief. Pleurisy is the rule, with plastic fibrinous exudate, which produces adhesions in healing. In these cases there may be more or less abundant effusion of serum, with greater or less admixture of leucocytes and fibrinous coagula. These effusions may fill loculi in the plastic exudate, to be finally absorbed, but protracting convalescence and delaying recovery. The effusion may rapidly reach large proportions, when, with but little invasion by leucocytes, we have the serous pleurisy, which is much less common in children than in adults. If, on the other hand, leucocytes are very abundant, empyema is the result, which is the usual form assumed at this period. Although these are generally extensive, they are yet limited by adhesions, so that in few, if any cases, is the entire pleural cavity filled with the purulent fluid. In these cases the fever declines, but does not disappear, at the time when convalescence usually takes place, to soon rise again, with an irregular curve. The pneumococcus is the organism present in these cases.

If allowed to pursue their natural course, the pus evacuates into a bronchus, or externally, with, after a prolonged and prevarious convalescence, complete or partial recovery, or the child is worn out and dies from exhaustion. Bearing in view the incidence of this complication, and the modifications of the ascultatory and percutory signs in children, these cases are usually recognizable. If in doubt, use the exploring exhaust needle without the slightest hesitation. As the result of sufficiently large experience, I desire to emphasize the importance of the facts here stated. It has been my observation that the great majority of cases of alleged "unresolved pneumonia" in children are, in fact, examples of empyema.

Otitis media, usually pneumococcic and purulent, is not rarely an important complication. It appears toward the end of or immediately after the pneumonic attack. One or both ears may be affected; rupture of the tympanic membrane is the rule; severe mastoiditis may occur; extension to the cerebral membranes or sinuses is rare. In these cases the mental dullness increases; [illegible] symptoms may appear; rigidity [illegible] ten, if not usually, present; tenderness is manifested when pressure is made on the lobe of the ear; recovery, without impairment of hearing, is the rule. Abscess, purulent pneumococcic pericarditis, peritonitis and arthritis are rare complications; ulcerative endocarditis and vascular thromboses are very rare.

The morbid anatomy of pneumonia in early life is modified by the structural and functional peculiarities appertaining to this period. The consolidation is clearly lobar, yet less prominently so than in the adult; it is also not so profound and the tissues are moister; the lobes are affected in a somewhat different proportion; resolution is more speedily completed.

Prognostically, pneumonia in the young is, at present, an unsolved problem. If conclusions are to be drawn from public health and institutional registration, it should be an exceedingly fatal affection; on the contrary, if we appeal to the results of our own clinical observations in private practice, especially of the better classes, I am of the opinion that this verdict must be revised and essentially modified; *id est*, that the fatality of pneumonia in the young is far below that of this malady in adults, and much less than is generally believed. In pneumonia at this period, as later, the changes of importance occur suddenly—the child gets better suddenly; gets worse suddenly; dies quickly and often unexpectedly; recovers promptly. Of the features of good import may be mentioned regularity of appearance and moderation of symptoms and course; absence of complications; slight or moderate virulency of the specific infecting germ. On the contrary, anomalous symptoms and erratic course; the appearance of serious complications; unusual virulency of the strain of pneumococcus, presage unusual or great danger. It is probable that recovery oftener follows an uncompromising assemblage of symptoms and conditions in the young than in those who are older.

The treatment of pneumonia may be faultlessly exemplary; it may be useless or harmless; it may be reprehensibly pernicious. The underlying principles of proper management may be stated, analyzed and formulated, but their application to meet the exigencies of the individual patient is an art which can not be transferred from one physician to another. In this field eminence in this art is attained only by those who have extraordinary native capacity, a broad foundation and keen perception of the pertinent facts and the advantages of lon[illegible]ars of practice. Failure is usually due to inherent incapacity, lack of necessary knowledge and restricted experience.

The fact that the pneumococcus in the blood and hepatized lung produce certain substances, which are as yet known only by their effects, e. g., the prompt occurrence of capillary dilatation and leucocytosis; later the appearance in the serum, within and without the blood vessels, of a specific agglutinin, and still later of a pneumococcic toxin, causing, within a short time, the disappearance from the blood of the pneumococcus, has led to the expectation that an antipneumonic serum would be produced which would promptly and directly cure the disease, but this has not been realized, although hope for the future remains.

Recently there have been made, by Drs. Welch and Rugh, in my wards some elaborate experiments, the objects of which were to demonstrate, if possible, the dynamic, not necessarily the curative, effects of the antipneumonic serums which are on the market. These observations are yet in progress and the facts have not yet been fully analyzed, but sufficient evidence has been obtained to warrant the conclusion that the effects are neither striking nor apparently important. The agglutinin is not noticeably increased; leucocytosis remains unaltered; the urinary chlorids are increased; the blood pressure is slightly augmented.

With our present knowledge it may be asserted that we have no specific for pneumonia; no agent which will certainly destroy the infecting organism nor render inert its toxins. However, there are certain prophylactic and remedial measures which are aimed directly at these points. For example: Keeping the pneumococcus-free child out of range of the infecting germ; avoiding exhaustion and too profound sleep in the pneumococcus-harboring child; cleansing the fluids of the body, intravascular and extravascular, of soluble toxins, in the pneumonic patient.

From the beginning the pneumonic child should be given liquids to drink as freely as they can be taken; in addition normal salt solution, modified possibly by the addition of coffee or other medicament, should be administered per rectum in such quantity and frequency as can be received, retained and absorbed. The presumption is that by these means the toxins in the blood and extravascular serosity is largely washed out, and that those which remain are greatly diluted. Theoretically, these devices should be useful; experimentally, we have no proof of their value; practically, I employ and advise them.

Beginning early, it is my practice to give moderate or large doses of a reliable tincture of digitalis, with the enemata if they are retained. Other vasomotor tonics and stimulants, e. g., caffein, adrenalin, etc., may be used.

If these little pneumonics have high fever, much dullness or restlessness, they are apparently made more comfortable, rational and normal by systematic sponge bathing. Personally, I prefer tepid sponging, followed by alcohol, repeated as often as required. This failing in its object, guaiacol, in suitable dosage, may be applied to the thin skin of the flexures as an efficient substitute. These may be advantageously supplemented by the ice-cap applied at intervals.

Oxygen inhalations are clearly useful when the patient is not fretted by their use. Strychnia, aromatic spirits of ammonia, etc., may be employed as required. In cases of profound nervous failure, with apathy, surface pallor, abdominal distension, the little patient may sometimes be aroused by a stimulating glycerinated enema.

The medical attention and nursing should be assiduous and of the highest quality. The child should be disturbed as little as possible compatible with necessary attention. The purest, freshest and most comportable air obtainable should be supplied.

Complications should receive prompt and careful attention, and in those requiring it (especially empyema) surgical relief should be given promptly.

DISCUSSION.

Dr. A. C. Cotton, Chicago, endorsed Dr. Wells' therapy in supplying salines. He thinks the time has come when clinically as well as theoretically we can appreciate the importance of maintaining the alkalinity of body fluids, especially in a disease like pneumonia with high temperature and intoxication. This should be done either by enteroclysis, normal salt solution, sodium bichlorid, or if necessary by hypodermoclysis of normal salt solution. If absolutely necessary, intravenous transfusion may be employed. Dr. Cotton considers this a point that will bear a great deal of emphasis and one which is too often neglected.

Dr. William J. Butler, Chicago, said that pneumonia may be either of the lobar or lobular type. The diagnosis of lobar pneumonia in infancy, he thinks, can not be regarded as difficult, though it is usually so considered. Too frequently overlooking a pneumonia is the result of failure to examine the patient. The clinical picture of lobar pneumonia in an infant is quite as typical as it is in the adult. The physical signs are likewise typical for the child. He called attention to one point especially important among the physical signs in infancy: The diminution in the respiratory murmur over the affected area, especially noticeable in the first twenty-four or forty-eight hours. This is frequently the only early physical sign that is evident. Associated with it, however, there usually is a varying grade of diminished resonance sometimes quite marked, even within the first twenty-four hours. Râles are not so frequently heard early in the infant, as they are at a later period of childhood or in adult life; in fact, they are infrequent. The diminished respiratory murmur, sometimes almost complete absence of it, with diminished percussion resonance, are the most conspicuous signs of beginning pneumonia in infants.

Dr. Butler thinks that rigidity of the neck in pneumonia can hardly be associated with middle ear disease, because it is a noticeable fact that in pneumonias during certain epidemics meningeal symptoms will sometimes predominate the whole clinical picture. In such cases middle ear disease may not be a noticeable factor. Middle ear disease does not manifest itself by opisthotonos in the young. He thinks, therefore, that physicians should continue to style this a pseudo-meningeal symptom.

Dr. T. L. Riley, New York City, has found that with the stethoscope modeled on the plan of the phonendoscope, in many of the so-called pneumonias in children, a diagnosis can be made twenty-four hours earlier than with the ordinary stethoscope. In lobar pneumonia in a child he does not think the mortality is more than 3 or 4 per cent. The pneumonia is not usually a true lobar pneumonia, but resembles catarrhal pneumonia. He thinks that it is customary to give up the old-fashioned poultices, but children generally find a great deal of comfort in these hot applications. Children and old people will generally tell you that they get more relief from these than from the use of an anodyne. The physician who loses the most pneumonia patients is the one who does not see his patients frequently.

Dr. Arthur W. Fairbanks, Boston asked Dr. Wells to what he attributes the extreme fetor sometimes seen in these cases. This is sometimes so extreme that it is scarcely possible to stay in the room with comfort and sometimes continues for two weeks. In some of these cases the temperature lasts several weeks, and there is some uncertainty in his mind whether they should be diagnosed as cases of possible pulmonary abscess.

Dr. John Lovett Morse, Boston, declared that in the young it is very important to differentiate between pneumonia in the infant and pneumonia in the child. Pneumonia in infancy is an extremely fatal disease, while in childhood it is a very mild one. He considers the pulse-respiration ratio the most important point in the diagnosis of pneumonia in infancy before the development of physical signs. When, in an infant, the rate of respiration is increased out of proportion to the rate of the pulse in an acute disease with a sudden onset and a high temperature, it is almost certainly indicative of pneumonia. In his experience, children with otitis media complicating pneumonia do not show symptoms pointing directly to the ear. The onset of trouble in the ear is more often shown by a rise in the temperature or else the child merely seems worse. Another point, he said, is the frequency with which the symptoms of pneumonia are referred by the child to the abdomen, or away from the lungs. Dr. Morse thinks that Dr. Wells did not emphasize sufficiently the importance of fresh air in the treatment. Dr. Morse put that first. If the patient has fresh air oxygen will rarely be needed. Dr. Morse does not use poultices except for relief of pain. It has been proved that heat and cold externally have no effect on the temperature or circulation in the pleural cavity. The recent work which has been done in France and in this country on the effect of chlorid of sodium when introduced into the system must be borne in mind. Physicians may be taking chances in giving large amounts of salt solution, as its action may be harmful instead of beneficial. Moreover, the heart is already under great strain and is bearing the brunt of the battle. Throwing a lot of fluid into the circulation makes the heart's work harder instead of relieving it.

Dr. A. C. Cotton, Chicago, said that when the right heart becomes overburdened, when dullness extends beyond the right sternal border two fingers' breadth in the fourth interspace, he believes it is time to extract a little blood from the circulation. This may be easily done by leeching, an old-fashioned procedure too frequently neglected. Relief for thirty-six or forty-eight hours may be secured by the application of from three to four leeches, in a child of 2 years, placed over the right hypochondria, and this procedure may be repeated at the end of forty-eight hours if necessary. Dr. Cotton said that he fully appreciates what has been said concerning the overloading of the heart with water, but he believes that the salines should be used by enteroclysis or by hypodermoclysis to meet the waste of alkalinity in the fluids.

Dr. Edward F. Wells, in reply to some remarks, said that in his opinion increasing the alkalinity of the blood in pneumonia is a procedure which may be useful, detrimental or innocuous. He has noted carefully the work which has been done along this line, and is sure that it is in the early stages of investigation, and that we have not sufficient facts before us at the present time to say whether or not we should increase, if possible, the alkalinity of the blood. It is well known that the pneumococcus grows most luxuriantly in an alkaline fluid, and that it produces an acid in its growth. Whether that acid should be neutralized or not is an open question. He intentionally omitted any mention of methods of treatment which are in this investigational period. In regard to increasing the sodium chlorid in the system, he said that this is another question which is in its investigational period. He believes, however, that inferentially it may be considered useful. One of the first and most important symptoms of pneumonia is the decline, as a rule almost to absence, of chlorids in the urine. This is more noticeable in the adult than in the infant, because of the naturally small proportion of chlorids in the urine in the latter. We may infer that this diminution of chlorids in the urine is because of the advantage that their retention might be in neutralizing toxins, or in some way acting as a defense to the system. He is in the habit of giving chlorids as freely as possible, but he does not advocate their intravenous injection. If the solution can not be borne by the stomach or rectum it can be introduced under the skin. He is familiar with the experimental work done in introducing chlorids in large quantities, and the alleged danger of producing edema thereby, yet he has no hesitation in pursuing the practice mentioned. In reply to Dr. Morse's criticism anent fresh air, Dr. Wells stated that he had emphasized the point as much as possible in stating that an abundance of comfortable pure air is of the highest importance. He said that he is not aware that there are any facts before us which can lead us for a moment to believe that uncomfortable air—overheated or overcooled—is more pure, more wholesome or more beneficial to the patient than that mentioned. He said that he wished to emphasize this point as much as he could, as he feels keenly on the subject. In reply to a question he stated that there is not sufficient evidence on which to base an opinion in regard to fetor of the breath. In some cases it is due to the fact that the child does not breathe through the nostrils. The mouth remains open and the secretions in the throat and nose become fetid. In Dr. Wells' experience the majority of cases in which there was rigidity of the neck were accompanied by otitis media, but in otitis media the neck is not uniformly rigid. Rigidity of the neck in his experience has been found most frequently in connection with otitis media. He thinks Dr. Riley's prognosis is too favorable and that his mortality is placed at too low a figure. Dr. Wells believes that what he has said about prognosis of pneumonia in the child, and the facts noted in the statistical portion of his paper will answer this portion of the discussion fully.

SURGICAL ASPECTS OF DISTURBED DENTITION OF THE THIRD MOLARS.*

M. L. RHEIN, M.D., D.D.S.,
Lecturer on Dental Pathology, University of Pennsylvania.
NEW YORK CITY.

The third molars generally make their appearance between the ages of sixteen and twenty. The final development of the length of the maxillæ posterior to the mental foramen in the lower jaw and maxillary sinus in the upper, takes place during this period, and in this manner sufficient space is provided for the proper alignment of the third molar when it breaks through the gum tissue. When this development proceeds without any disturbing constitutional causes, no difficulties attend the eruption of these teeth. As, however, all inflammatory actions that arise during this period either from local pathologic causes or by virtue of constitutional disturbances, have a marked effect on the osseous development of these parts we find the normal type of development to be the exception. These departures from a purely normal type vary greatly according to the amount of disturbance that has taken place, and in a large number of cases interfere with the normal eruption of the third molars. This interference with the eruption of these teeth is confined more particularly to the lower jaw. The reason for the lower third molar being exceptionally liable to serious disturbances is due to the difference in the anatomy of the two jaws. On account of the limitations of time and small percentage of troubles encountered with erupting upper molars, these remarks will be confined strictly to the inferior teeth.

The necessity for sufficient room at the angle of the body and the ramus is shown in Fig. 1 (Crver). Fig. A shows the mandible of one of the Fan tribe of West Africa, and there is abundance of room for the third molar. Fig. B is a picture of a Caucasian lower jaw of normal type where there is just barely sufficient room for the third molar. The lessening of this amount of space is one of the most prolific sources of disturbed dentition in this locality. Too frequently there is no room left between the second molar and the ramus, and as a result the third molar finally erupts in some unusual position. During this effort at unnatural eruption, grave disturbances are very liable to occur. The close proximity of the cribriform tube (Fig. 2, Cryer) to the roots of the third molar, is another anatomic feature which has a marked bearing on the etiology of disturbances in this region. In many anatomic specimens the incompleted roots can be seen penetrating the canal itself. The cribriform tube or inferior dental canal (Fig. 3, Cryer) furnishes a pathway of a light resistance to infection, and once involved leads to serious septic conditons. Another marked pathologic condition that results from the close proximity to the inferior dental nerve is that the irritation of this nerve is very likely to produce a stimulation in nutritional supply at this point, so that the normal cancellated bone (Fig. 4, Cryer) through which the erupting tooth can readily force its way, is replaced by the hardest of osseous structure which attempts to force the tooth aside to seek some easy but unnatural mode of eruption. This excitation of bony development sometimes proceeds to such extremes as to encapsulate the tooth in a dense bony cyst in which it becomes impacted (Fig. 5, Cryer). The study of this condition will not be considered at this time, but it is merely mentioned as a possible result where this undue eruption proceeds to its extreme limit.

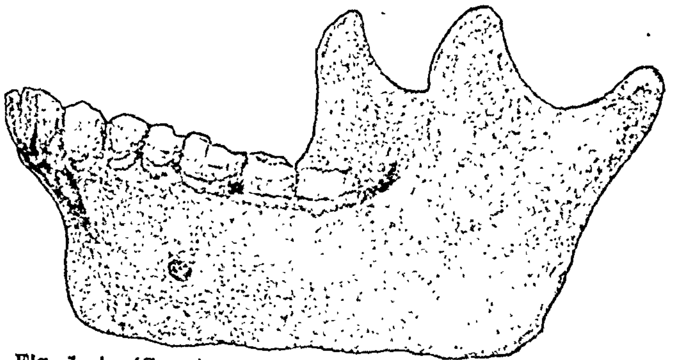

Fig. 1 A. (Cryer).—Mandible of a member of the Fan tribe, West Africa, showing abundance of room for third molar.*

The unnatural increase in osteoblasts with all the attending inflammatory conditions, produces a marked effect on all the surrounding tissue. The resistance is depressed in proportion to the degree of irritation and this is also further influenced by any disturbances of the general system. When this decreased resistance has reached a certain stage, the parts become an easy prey to infection. In this way, we find the eruption of the third molar which should be a natural physiologic action, complicated by more or less severe pathologic disturbances.

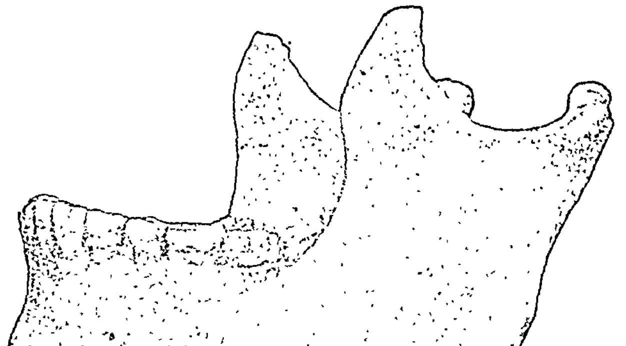

Fig. 1 B. (Cryer).—A Caucasian lower jaw of modern type, with barely sufficient room for third molar.

Another etiologic factor that sometimes plays an important rôle in depressing the local vitality, is found in mouths where on occlusion the two jaws come so close together that traumata of the gums over the erupting tooth are constantly taking place, caused by the upper teeth constantly biting the gum tissue over the erupting tooth, and infection frequently ensues.

Another marked point of irritation is found in such mouths where on account of lack of space between the second molar and the ramus, the third molar is pushed forward, and its eruption is impeded by coming in contact with the distal side of the second molar. Frequently, only the slightest impingement on the territory of the second molar will start up an inflammatory action, and the parts become rapidly infected.

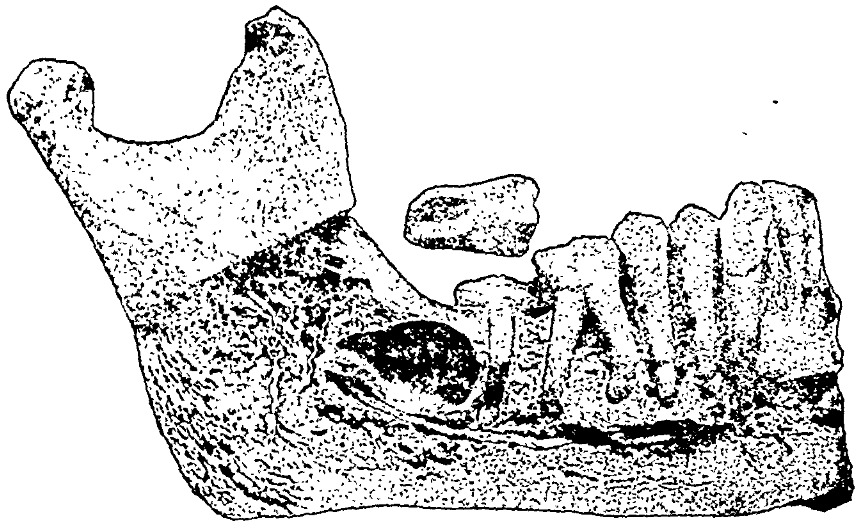

Fig. 2 (Cryer).—Close proximity of cribriform tube to root of third molar.

Since 1828, when Toirac gave the first accurate description of this disturbance, French and German authorities have written extensively on this subject. In 1878 Heydenreich reviewed the list of writers on this subject up to that date. According to Magitot (1879) and David, complications ensue in the eruption of 75 per cent. of third lower molars. Some very unique etiologic theories are advanced by some of these authorities. Moty,[1] in 1901, tried to show an analogy between suppurating dermoid cysts and infections of erupting third molars. He found the cause at the end of the root, and speaks of it as an "epithelial inclusion," and it will be instructive to quote from him. He says:

> In our opinion, these phlegmons are due entirely to a collection of epithelial cells enclosed at the bottom of the alveolus. This enclosed epithelium is found as a fungous mass which has gradually infiltrated the wall of the alveolus without enlarging the latter. In some cases, this neoplastic tissue becomes encysted. In nearly all cases these epithelial inclusions cause abcesses at the time of eruption of the wisdom teeth or later on. Early extraction may be necessary on account of the pain even before suppuration has set in, but the latter invariably occurs in cases left to themselves. The cause

[1] Moty: Accidents de la dent de sagesse Rev. de Chirurg., vol. 23, 1901, p. 617.

of this non-bacterial suppuration is due entirely to these cells acting as a foreign body.

Epithelial inclusions may be found with other teeth, but only rarely. It is very probable that the enamel body may leave an epithelial focus in the gums which may develop into a tooth (giving rise to a third dentition). These cases themselves are very rare, but grouped with other anomalies (single cusps, an additional cusp or round root added to a molar, large tooth, extra tooth not growing from the gums, etc.) make a large class. Abscesses associated with healthy wisdom teeth and commencing in the depth of the alveolus are sterile. The pus has no bad odor unless a secondary infection has supervened. An odor generally indicates a carious tooth.

If views such as these are correct, it upsets all our ideas of the pathogenic conditions at work in these cases. It is wise, however, to have our attention directed to the different views that are held on this subject, and I have quoted the latter one because it is remarkably well expressed.

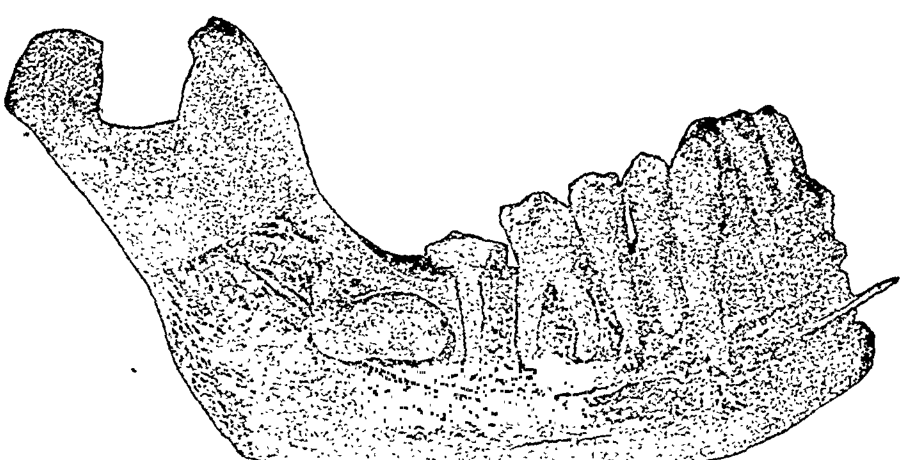

Fig. 5 (Cryer).—Tooth encapsulated in dense bony cyst.

Careful observation of clinical data impresses us with the view that there are many predisposing factors to be considered in the etiologic study of different cases.

For the sake of convenience, the subject can be considered in two divisions: First, disturbances which antedate the appearance of the tooth; second, those which take place after the partial eruption of the tooth. Symptoms in the early stages are not much more marked than in ordinary physiologic dentition. There is the usual amount of pain accompanied by congestion of the gums overlying the erupting tooth. The edema becomes more marked, rapidly progressing in every direction and involving the pillars of the fauces and the various glands in the mouth. Neuralgic pains radiate to the ear and eye, and as the submaxillary glands become involved, they extend to the neck, to the shoulders, and even to the arms. The patient finds it more and more difficult to open the mouth. As infection progresses, the pulse becomes more rapid, and temperature may rise even to 103 degrees. A careful digital examination over the gums will readily detect the presence of the tooth underneath. In some cases, the gum becomes attenuated and pale as in ordinary dentition; as a rule, however, this is not the case, but the opposite condition results, which is that of excessive congestion.

Prompt excision of the entire hood of gum tissue is at once called for. The resection of the gum should be so thorough as completely to expose the four sides of the tooth. Many authorities recommend the cautery for this purpose, but the knife is a more valuable adjunct, as the blood-letting itself is very beneficial. Every possible means should now be used to aid in the rapid eruption of the tooth, and the prevention of re-infection of the parts. Foreign writers all unite in a plea for extraction as the only radical cure in these cases. Whenever it becomes evident that the third molar, by reason of its irregular position and a lack of space in the jaw for its proper berth, can never become a useful organ, the earliest extraction of the tooth is called for.

On the other hand, in a large percentage of cases, the tooth can be brought into proper alignment and occlusion, and under such circumstances there is no valid excuse for its extraction. A strip of gauze should be packed between the gum and tooth around its entire circumference. In case of the second molar acting as an obstruction, this gauze will act to some extent as a wedge in making a proper place for the third molar. The gauze packing should be frequently changed. If possible, the mouth should be sprayed at intervals with a hot borated wash, which at any rate should be used by the patient frequently as a mouth lotion. The focus of infection in most cases under sufficiently energetic treatment will soon find an outlet either into the mouth or the fauces, and the symptoms will rapidly abate.

The trismus, paralysis and edema in these cases involve so much surrounding territory that they are frequently mistaken by the medical attendant for adenitis, stomatitis, pyorrhea, parotitis and diseases due to the condition of other teeth. An error in diagnosis in these cases generally means an error in treatment, and usually results in an unnecessary disfigurement of the face. The frequency of errors in diagnosis of these cases is one of the strongest pleas that can be made for the education of medical men in the principles of dentistry.

The following notes taken from a typical case will illustrate this fact:

Patient.—Miss A., between the age of 16 and 17, had been convalescing for two weeks from an attack of measles, when she commenced to have paroxysms of pain in the posterior portion of the mouth; this was accompanied by edema, and a steadily rising temperature.

History.—The physician who had attended her was sent for, and he made a diagnosis of adenitis of the submaxillary glands. The temperature twenty-four hours later had risen to 102.5 F., and her pulse was 120. Under his direction Credés ointment was liberally spread over the neck at the angle of the jaw, and this was covered by rubber tissue. The expectation of the attending physician was that the absorption of the silver salt would arrest the infective infiltration. The result, however, was that it acted as a poultice, and drew the inflammation and infection within the mouth to the outer tissues. Forty-eight hours after this treatment had been commenced, I was called to see the patient because the mother had a suspicion that the teeth might be involved; the patient having continuously complained of pain at the angle of the body and the ramus of the mandible.

Examination.—I found the patient suffering severely from neuralgic pains, with a great amount of edema, extending through the entire cervical region, and involving most of the hyoid muscles. A very careful external examination failed to discover any sign of any glandular enlargement, but simply an edema penetrating through all the tissues. On this account it was difficult for the patient to open her mouth, yet a careful digital examination over the mandible between the second molar and the ramus, readily distinguished the outlines of an erupting third molar.

Treatment.—The case being turned over to me, I at once dissected away the entire hood of gum tissue which was covering the erupting tooth, and found that the mesial approximal surface of the third molar was impinging slightly on the distal approximal contour of the second molar. Iodoform gauze was packed around the entire circumference of the tooth, especial attention being paid to the space between the second and third molar.

Result.—The temperature of the patient dropped immediately to 100.5, and the pulse to 100. Naturally, the ointment and rubber tissue were at once removed from the neck, and hot borinated mouth lavations were ordered every fifteen minutes with the hope of bringing the inflammatory action back again into the oral cavity. A blood count showed 20,000 leucocytes.

The patient was constantly under the care of a trained nurse, and for the following five days, the temperature varied between 99.8 and 101. At this time results of the treatment prevailed, and a purulent effusion made its escape from the tonsils. The packing of the gauze between the two molars was persisted in for about ten days, when sufficient space between the two teeth was obtained, and the third molar was finally erupted into a position of correct occlusion and alignment.

The most serious type of cases are those in which disturbances do not abate after partial eruption of the tooth has taken place. Writers frequently speak of the purulent troubles of third molars that exist even after eruption of the tooth has been completed, but careful anatomic examination will generally show that the eruption of the tooth has not been entirely completed, some obstacle being present which prevents the tooth coming out as it naturally would. This is the class of cases that Moty speaks of in which he classifies the cause as an "epithelial inclusion."

The undue osteoblastic stimulation that would result from the inflammatory action present in these cases, is sufficient to account for this condition which he so graphically describes as "epithelial inclusion," but which is nothing more than an over stimulation of peridental membrane, which, if persisted in, frequently leads to a complete ossification of the parts, and produces an impacted tooth.

In all these cases, every effort should be made in the line of proper orthodontia, so that if possible the tooth can be properly erupted and preserved. The value of the retention of the third molar in a mandible large enough to contain it, should never be overlooked. If, however, it is found impossible to bring the tooth to its proper height and alignment, extraction should be resorted to at the very earliest moment. In such cases it makes no difference how difficult it is to extract the tooth, if necessary deep narcosis must be resorted to, and a portion of the mandible cut away so as to remove every portion of the tooth. The longer there is any delay in such cases, the greater is the danger of severe neuralgic complications and infiltrative osteomyelitis through the inferior dental canal. For this same reason, if extraction of such a tooth has taken place, the greatest care should be taken to keep the wound packed with sterile gauze in order to avoid re-infection which may lead by means of the cribriform tube, to an extensive osteomyelitis. The same rule obtains in cases of abscessed or necrotic conditions in which there is any danger of re-infection and especially where the field of operation is in close proximity to any of the osseous sinuses. This does not necessarily include healthy alveolar sockets in other parts of the jaws.

The following clinical case will illustrate the danger resulting from neglecting to attend to the sterilization of such a socket:

Patient.—Mr. S., bachelor, aged about 30, had a third molar extracted which had never completely erupted, but had been a constant source of irritation for many years. The extraction was performed by a specialist in this line, and was said to have been a very difficult one. The later surgical operation demonstrated definitely that the roots of the third molar penetrated the cribriform tube as shown in Figure 2. (Cryer). Inadequate attention to keeping the wound sterile (no packing having been used) was followed by an infection in the alveolar sockets. This spread without any difficulty to the inferior dental canal, and when I saw the patient for the first time in the hospital on July 3, 1900, in consultation with Dr. Howard Lilienthal, he was not far from a moribund state. There was a very rapid and weak pulse, with temperature of 105.5 F.

Diagnosis.—An infiltrative osteomyelitis progressing through the passageway of the cribriform tube.

Treatment.—The patient was immediately anesthetized, and an external incision made at the angle of the body and the ramus. The bone was chiseled away at this point until the interior of the tube was exposed, when there was an effusion of a large mass of purulent matter, grayish in color, and of most foul odor. The condition of the patient at this time was so serious that the operation was made as short and performed as rapidly as possible, great fear being entertained that he would not survive the ordinary surgical shock. Drainage was established through the external opening thus obtained, and the recovery was very slow. It soon became evident that an entire infected zone of bone had not been removed, and on October 27, a subperiosteal resection was performed, extending from the symphysis of the body to a considerable portion of the ascending ramus. After this, the case went on to complete recovery.

Figures 3 and 4, taken from Cryer, will illustrate most beautifully the parts operated on. The prognosis in such cases is remarkably good, as long as correct surgical principles are used in the operative procedure.

SUMMARY.

It would appear that the medical profession are sometimes remiss in their failure to call on stomatologists for consultation in obscure cases of infection in the oral regions. Errors of diagnosis have been the cause of numerous cases of unnecessary facial disfigurement.

On the other hand, stomatologists should realize the value of retaining all the molars if possible. When extraction has to be resorted to, too much and too harsh a criticism can not be used against those practitioners of this specialty who are negligent in taking proper precautions against infection of wounds in this locality.

38 East Sixty-first Street.

DISCUSSION.

Dr. Eugene Talbot, Chicago, said that the line of research work which he has carried on in the last five years is based on the law of economy of growth, i. e., a structure is lost for the benefit of the organs as a whole. Later this law was modified and called the "use and disuse of structures." The appendix, pineal body, etc., are examples of these changes in the evolution of man. In the development of the brain certain structures must pass, and the face, jaws and teeth will suffer. The law of evolution is so fixed that there is no pathologic condition about the face, jaws and teeth but comes under it. This change has been going on ever since the world began and is still continuing. The use of specially prepared flour and coarse foods will not benefit the teeth. If methods of living could be changed from generation to generation, possibly with the mixture of races, in a thousand or more years the jaws might develop and the teeth become dense in structure, but this evolution is going on and a man who has thirty-two well-developed teeth to-day in perfect condition is an atavism. As advance in evolution proceeds degenerates are going to develop faster. Decay of the teeth is increasing and will never be stopped by our present methods.

Dr. M. I. Schamberg, Philadelphia, stated that these retrograde changes are going on all the time, and impacted teeth are becoming more prevalent. There is scarcely a week that he does not see wisdom teeth in a marked degree of impaction. Dr. Schamberg did not altogether agree with the authority quoted by Dr. Rhein. He describes the impaction which takes place around the wisdom teeth as due to non-septic pus. Dr. Schamberg knows of no such condition. He believes that the non-septic cyst which is often found at the end of the teeth is frequently mistaken for an abscess. It does not become an abscess until there is bacterial infection. The same is true of these cases of delayed eruption of wisdom teeth, in which there may be serum formed, but the infection spread through the maxillary region is not due to serum, but takes place only after bacterial infection. Often the angle of the jaw comes off so close that a portion of the gum is forced over the tooth, and food may be forced under this, forming a pocket of infection. In teeth erupting in improper positions there is great danger in endeavoring to straighten them by pressing backward on the inferior dental canal.

Dr. F. L. Platt, San Francisco, said he thinks there are circumstances in which the third molar may be saved to advantage, but in the majority of cases, unless they are desired for the support of bridge work, or partial dentines, the lower third molars would better be extracted. Very few people clean their teeth properly, the vast majority never reaching the third molar. In many cases Dr. Platt has found molars that were exceedingly dirty in mouths otherwise well cared for. The soft tissue comes down close behind the third molar, the buccal tissues overlap it, and it is frequently the seat of infection and decay, and this leads to decay of the distal surface of the second molar tooth. Unless there is plenty of room for the lower third molars, and unless they occlude properly, it is the best practice to extract them. They are of no benefit to the patient, therefore can be no loss, and many good second molars in this way might be saved.

Dr. J. S. Marshal, San Francisco, said that of course dentists all realize the result of present civilization has been to increase the size of the brain and to shorten the jaw, and to produce more or less crowding of the teeth, and that we are expecting as a result that the third molar will finally disappear, but he is not sure that this can be considered a process of evolution. He is inclined to think that these conditions are more the result of intermixture of races and nations. He had an opportunity a few years ago to examine some skulls of ancient Britons, Romans, Saxons and Danes. With very few exceptions he found no malformation so far as arrangement of the teeth was concerned, but a few centuries later the skulls of English people (made up from the intermixture of the above races), show many irregularities in the alignment of the teeth; the jaws are shorter, there is crowding of the teeth, so that the third molar is out of position or suppressed. He believes that after a few thousand years these things will adjust themselves, and teeth will return to a normal type. He does not believe that as a race we are eventually going to lose our teeth. He thinks Nature will correct these conditions. The composite photograph of the head and face of the American college girl will be the perfected type, and Dr. Marshal believes we are gradually coming to this. When this condition is brought about there will be perfect harmony in the relations of brain, jaws and teeth.

Dr. G. V. I. Brown, Milwaukee, agreed with Dr. Rhein in making an effort to save the third molars. He believes that is a part of our work. Obviously the only way to prevent this difficulty with the third molar is to begin with the individuals before the time of eruption and make room. Dentists must do artificially what Nature fails to do. Whether we are going to have teeth a generation or two from now is interesting in the abstract, but does not cut any special figure in our practices. The trouble with the third molar in most instances is that it wants more room. If we can provide this the proper eruption of the tooth will become a much less serious question. Most dentists, and particularly those who extract without proper care and appliances, and without reasonable possibility of anything like asepsis, go into one of the most critical regions without due preparation. One difficulty in taking proper precautions is that patients think dentists magnify the seriousness of the condition. If all dentists would be rigid about this it would make it easier.

Dr. M. L. Rhein said that Dr. Schamberg fell into error in imagining that he was supporting the views of Dr. Moty of Paris. Dr. Rhein quoted from Moty because he is under the impression Moty is a French authority, and he stated in his paper that if these views were correct dentists would have to change their ideas on this subject. Many European writers agree with Dr. Schamberg in not trying to save the third molars. Dr. Rhein does not want the impression to go out that he is saving all these third molars. As soon as it is evident that the third molar can not be brought to correct occlusion and alignment, extraction should be performed. It is the tendency of the teeth later in life, when approaching senility, to move backward, and the third molar when in position is a sort of back-stop to the second molar, and consequently to the ful organ, the earliest extraction of the tooth is called for.

On the other hand, in a large percentage of cases, the tooth can be brought into proper alignment and occlusion, and under such circumstances there is no valid excuse for its extraction. A strip of gauze should be packed between the gum and tooth around its entire circumference. In case of the second molar acting as an obstruction, this gauze will act to some extent as a wedge in making a proper place for the third molar. The gauze packing should be frequently changed. If possible, the mouth should be sprayed at intervals with a hot borated wash, which at any rate should be used by the patient frequently as a mouth lotion. The focus of infection in most cases under sufficiently energetic treatment will soon find an outlet either into the mouth or the fauces, and the symptoms will rapidly abate.

The trismus, paralysis and edema in these cases involve so much surrounding territory that they are frequently mistaken by the medical attendant for adenitis, stomatitis, pyorrhea, parotitis and diseases due to the condition of other teeth. An error in diagnosis in these cases generally means an error in treatment, and usually results in an unnecessary disfigurement of the face. The frequency of errors in diagnosis of these cases is one of the strongest pleas that can be made for the education of medical men in the principles of dentistry.

The following notes taken from a typical case will illustrate this fact:

Patient.—Miss A., between the age of 16 and 17, had been convalescing for two weeks from an attack of measles, when she commenced to have paroxysms of pain in the posterior portion of the mouth; this was accompanied by edema, and a steadily rising temperature.

History.—The physician who had attended her was sent for, and he made a diagnosis of adenitis of the submaxillary glands. The temperature twenty-four hours later had risen to 102.5 F., and her pulse was 120. Under his direction Credés ointment was liberally spread over the neck at the angle of the jaw, and this was covered by rubber tissue. The expectation of the attending physician was that the absorption of the silver salt would arrest the infective infiltration. The result, however, was that it acted as a poultice, and drew the inflammation and infection within the mouth to the outer tissues. Forty-eight hours after this treatment had been commenced, I was called to see the patient because the mother had a suspicion that the teeth might be involved; the patient having continuously complained of pain at the angle of the body and the ramus of the mandible.

Examination.—I found the patient suffering severely from neuralgic pains, with a great amount of edema, extending through the entire cervical region, and involving most of the hyoid muscles. A very careful external examination failed to discover any sign of any glandular enlargement, but simply an edema penetrating through all the tissues. On this account it was difficult for the patient to open her mouth, yet a careful digital examination over the mandible between the second molar and the ramus, readily distinguished the outlines of an erupting third molar.

Treatment.—The case being turned over to me, I at once dissected away the entire hood of gum tissue which was covering the erupting tooth, and found that the mesial approximal surface of the third molar was impinging slightly on the distal approximal contour of the second molar. Iodoform gauze was packed around the entire circumference of the tooth, especial attention being paid to the space between the second and third molar.

Result.—The temperature of the patient dropped immediately to 100.5, and the pulse to 100. Naturally, the ointment and rubber tissue were at once removed from the neck, and hot borinated mouth lavations were ordered every fifteen minutes with the hope of bringing the inflammatory action back again into the oral cavity. A blood count showed 20,000 leucocytes.

The patient was constantly under the care of a trained nurse, and for the following five days, the temperature varied between 99.8 and 101. At this time results of the treatment prevailed, and a purulent effusion made its escape from the tonsils. The packing of the gauze between the two molars was persisted in for about ten days, when sufficient space between the two teeth was obtained, and the third molar was finally erupted into a position of correct occlusion and alignment.

The most serious type of cases are those in which disturbances do not abate after partial eruption of the tooth has taken place. Writers frequently speak of the purulent troubles of third molars that exist even after eruption of the tooth has been completed, but careful anatomic examination will generally show that the eruption of the tooth has not been entirely completed, some obstacle being present which prevents the tooth coming out as it naturally would. This is the class of cases that Moty speaks of in which he classifies the cause as an "epithelial inclusion."

The undue osteoblastic stimulation that would result from the inflammatory action present in these cases, is sufficient to account for this condition which he so graphically describes as "epithelial inclusion," but which is nothing more than an over stimulation of peridental membrane, which, if persisted in, frequently leads to a complete ossification of the parts, and produces an impacted tooth.

In all these cases, every effort should be made in the line of proper orthodontia, so that if possible the tooth can be properly erupted and preserved. The value of the retention of the third molar in a mandible large enough to contain it, should never be overlooked. If, however, it is found impossible to bring the tooth to its proper height and alignment, extraction should be resorted to at the very earliest moment. In such cases it makes no difference how difficult it is to extract the tooth, if necessary deep narcosis must be resorted to, and a portion of the mandible cut away so as to remove every portion of the tooth. The longer there is any delay in such cases, the greater is the danger of severe neuralgic complications and infiltrative osteomyelitis through the inferior dental canal. For this same reason, if extraction of such a tooth has taken place, the greatest care should be taken to keep the wound packed with sterile gauze in order to avoid re-infection which may lead by means of the cribriform tube, to an extensive osteomyelitis. The same rule obtains in cases of abscessed or necrotic conditions in which there is any danger of re-infection and especially where the field of operation is in close proximity to any of the osseous sinuses. This does not necessarily include healthy alveolar sockets in other parts of the jaws.

The following clinical case will illustrate the danger resulting from neglecting to attend to the sterilization of such a socket:

Patient.—Mr. S., bachelor, aged about 30, had a third molar extracted which had never completely erupted, but had been a constant source of irritation for many years. The extraction was performed by a specialist in this line, and was said to have been a very difficult one. The later surgical operation demonstrated definitely that the roots of the third molar penetrated the cribriform tube as shown in Figure 2. (Cryer). Inadequate attention to keeping the wound sterile (no packing having been used) was followed by an infection in the alveolar sockets. This spread without any difficulty to the inferior dental canal, and when I saw the patient for the first time in the hospital on July 3, 1900, in consultation with Dr. Howard Lilienthal, he was not far from a moribund state. There was a very rapid and weak pulse, with temperature of 105.5 F.

Diagnosis.—An infiltrative osteomyelitis progressing through the passageway of the cribriform tube.

Treatment.—The patient was immediately anesthetized, and an external incision made at the angle of the body and the ramus. The bone was chiseled away at this point until the interior of the tube was exposed, when there was an effusion of a large mass of purulent matter, grayish in color, and of most foul odor. The condition of the patient at this time was so serious that the operation was made as short and performed as rapidly as possible, great fear being entertained that he would not survive the ordinary surgical shock. Drainage was established through the external opening thus obtained, and the recovery was very slow. It soon became evident that an entire infected zone of bone had not been removed, and on October 27, a subperiosteal resection was performed, extending from the symphysis of the body to a considerable portion of the ascending ramus. After this, the case went on to complete recovery.

Figures 3 and 4, taken from Cryer, will illustrate most beautifully the parts operated on. The prognosis in such cases is remarkably good, as long as correct surgical principles are used in the operative procedure.

SUMMARY.

It would appear that the medical profession are sometimes remiss in their failure to call on stomatologists for consultation in obscure cases of infection in the oral regions. Errors of diagnosis have been the cause of numerous cases of unnecessary facial disfigurement.

On the other hand, stomatologists should realize the value of retaining all the molars if possible. When extraction has to be resorted to, too much and too harsh a criticism can not be used against those practitioners of this specialty who are negligent in taking proper precautions against infection of wounds in this locality.

DISCUSSION.

Dr. Eugene Talbot, Chicago, said that the line of research work which he has carried on in the last five years is based on the law of economy of growth, i. e., a structure is lost for the benefit of the organs as a whole. Later this law was modified and called the "use and disuse of structures." The appendix, pineal body, etc., are examples of these changes in the evolution of man. In the development of the brain certain structures must pass, and the face, jaws and teeth will suffer. The law of evolution is so fixed that there is no pathologic condition about the face, jaws and teeth but comes under it. This change has been going on ever since the world began and is still continuing. The use of specially prepared flour and coarse foods will not benefit the teeth. If methods of living could be changed from generation to generation, possibly with the mixture of races, in a thousand or more years the jaws might develop and the teeth become dense in structure, but this evolution is going on and a man who has thirty-two well-developed teeth to-day in perfect condition is an atavism. As advance in evolution proceeds degenerates are going to develop faster. Decay of the teeth is increasing and will never be stopped by our present methods.

Dr. M. I. Schamberg, Philadelphia, stated that these retrograde changes are going on all the time, and impacted teeth are becoming more prevalent. There is scarcely a week that he does not see wisdom teeth in a marked degree of impaction. Dr. Schamberg did not altogether agree with the authority quoted by Dr. Rhein. He describes the impaction which takes place around the wisdom teeth as due to non-septic pus. Dr. Schamberg knows of no such condition. He believes that the non-septic cyst which is often found at the end of the teeth is frequently mistaken for an abscess. It does not become an abscess until there is bacterial infection. The same is true of these cases of delayed eruption of wisdom teeth, in which there may be serum formed, but the infection spread through the maxillary region is not due to serum, but takes place only after bacterial infection. Often the angle of the jaw comes off so close that a portion of the gum is forced over the tooth, and food may be forced under this, forming a pocket of infection. In teeth erupting in improper positions there is great danger in endeavoring to straighten them by pressing backward on the inferior dental canal.

Dr. F. L. Platt, San Francisco, said he thinks there are circumstances in which the third molar may be saved to advantage, but in the majority of cases, unless they are desired for the support of bridge work, or partial dentines, the lower third molars would better be extracted. Very few people clean their teeth properly, the vast majority never reaching the third molar. In many cases Dr. Platt has found molars that were exceedingly dirty in mouths otherwise well cared for. The soft tissue comes down close behind the third molar, the buccal tissues overlap it, and it is frequently the seat of infection and decay, and this leads to decay of the distal surface of the second molar tooth. Unless there is plenty of room for the lower third molars, and unless they occlude properly, it is the best practice to extract them. They are of no benefit to the patient, therefore can be no loss, and many good second molars in this way might be saved.

Dr. J. S. Marshal, San Francisco, said that of course dentists all realize the result of present civilization has been to increase the size of the brain and to shorten the jaw, and to produce more or less crowding of the teeth, and that we are expecting as a result that the third molar will finally disappear, but he is not sure that this can be considered a process of evolution. He is inclined to think that these conditions are more the result of intermixture of races and nations. He had an opportunity a few years ago to examine some skulls of ancient Britons, Romans, Saxons and Danes. With very few exceptions he found no malformation so far as arrangement of the teeth was concerned, but a few centuries later the skulls of English people (made up from the intermixture of the above races), show many irregularities in the alignment of the teeth; the jaws are shorter, there is crowding of the teeth, so that the third molar is out of position or suppressed. He believes that after a few thousand years these things will adjust themselves, and teeth will return to a normal type. He does not believe that as a race we are eventually going to lose our teeth. He thinks Nature will correct these conditions. The composite photograph of the head and face of the American college girl will be the perfected type, and Dr. Marshal believes we are gradually coming to this. When this condition is brought about there will be perfect harmony in the relations of brain, jaws and teeth.

Dr. G. V. I. Brown, Milwaukee, agreed with Dr. Rhein in making an effort to save the third molars. He believes that is a part of our work. Obviously the only way to prevent this difficulty with the third molar is to begin with the individuals before the time of eruption and make room. Dentists must do artificially what Nature fails to do. Whether we are going to have teeth a generation or two from now is interesting in the abstract, but does not cut any special figure in our practices. The trouble with the third molar in most instances is that it wants more room. If we can provide this the proper eruption of the tooth will become a much less serious question. Most dentists, and particularly those who extract without proper care and appliances, and without reasonable possibility of anything like asepsis, go into one of the most critical regions without due preparation. One difficulty in taking proper precautions is that patients think dentists magnify the seriousness of the condition. If all dentists would be rigid about this it would make it easier.

Dr. M. L. Rhein said that Dr. Schamberg fell into error in imagining that he was supporting the views of Dr. Moty of Paris. Dr. Rhein quoted from Moty because he is under the impression Moty is a French authority, and he stated in his paper that if these views were correct dentists would have to change their ideas on this subject. Many European writers agree with Dr. Schamberg in not trying to save the third molars. Dr. Rhein does not want the impression to go out that he is saving all these third molars. As soon as it is evident that the third molar can not be brought to correct occlusion and alignment, extraction should be performed. It is the tendency of the teeth later in life, when approaching senility, to move backward, and the third molar when in position is a sort of back-stop to the second molar, and consequently to the other teeth. It becomes a question of the view of the practitioner in every case. He should know when to extract and when to try to save. Dr. Rhein's practice is distinctly a family one and unless his patients are willing to abide by his decision he will not treat them. If they will not keep their mouths in a hygienically clean condition he does not waste his services. Patients are largely what dentists make them, and if the dentist can not train them properly we should not take charge of them.

CHOLERA AND INFECTED WATERS.[*]

CHARLES E. WOODRUFF, M.D.
Major and Surgeon U. S. Army.
PLATTSBURG BARRACKS, N. Y.

The experience gained by the American military surgeons during the Philippine cholera epidemic of 1902 and 1903 has enabled them to correct a few errors in the current theories as to the methods of the spread of this dreadfully fatal disease. From their knowledge of the biologic characters of the spirillum, they were forced into an investigation, first, of the manner in which the living germ was transported into uninfected territory, and, second, of the manner in which it was carried from patient to patient after it was planted in this new territory. The spirillum is a very frail organism, which leads practically a parasitic existence, for it soon perishes outside of the host. Experimentally, it has been determined that it is killed in five minutes by a temperature of 80 C., in two hours by drying, and more quickly still if dried in the sunlight. Hence, as an invariable rule, the living moist germ is carried from place to place either in an infected host or as a culture on moist foods.

It would, then, apparently be a simple matter to trace up the channel of infection, yet all the investigations were hampered by the remarkable difficulty of eliciting truthful information from the patient. It was first supposed that this was merely the characteristic of the Malay, who is notorious for the skill he possesses in evading the truth in his remarks on any topic when he imagines that the truth will react against him. It was found that in American sufferers also it was an extremely difficult matter to get them to confess where they had been eating or drinking. They may have been ashamed to confess that they had been so foolish as to violate sanitary regulations deliberately, but it was doubtless due, in great part if not entirely, to the interruption of the cerebral circulation, which made clear thinking impossible. It is not true that the patients are clear-headed in the throes of this disease, as so often reported.

Investigators, therefore, were compelled to resort to indirect evidence as to sources of infection and methods of spread. Almost invariably it was found that the first case in a new territory was a newcomer who had been infected elsewhere and who showed symptoms very shortly after his arrival. The short period of incubation made this evidence stand out with startling clearness. It is but a few hours after swallowing the germ that symptoms appear, and frequently patients were dead less than twenty-four hours after infection. The shortest case is said to have been ten hours from infection to the first symptoms. Hence, the traveler who brings the infection into a new neighborhood is usually desperately sick on arrival, and a patient is known to have died fifteen minutes after he left a railroad car in which he had been travelling but an hour and a half.

We can safely say that practically the only way the infection is carried into a new territory is by infected travelers, for the other methods are so rare as to be mere curiosities. Yet foods are now and then the vehicle; for instance, in one town the first eighty cases were directly traced to a fiesta or banquet in which the food was supplied by a native caterer. He cooked the material in Manila, where it was undoubtedly infected, and then smuggled it into the distant town. It proved to be a splendid culture medium, so that when served it was no doubt swarming with spirilla. The cook himself died shortly after arrival and was probably infected from the same source which infected the food.

Curiously enough, it was probably by this rare method that cholera was introduced into the Philippine Islands from China, where the disease had been epidemic a long time. In the Orient, where intensive cultivation is carried to an extreme, human feces and urine are carefully collected and sold to the farmer as fertilizers. They are mixed with water and then sprinkled by watering pots on the leaves, so that a garden in China or Japan is a most foul smelling landscape to which distance lends enchantment. The result is evident. If there is cholera, typhoid, dysentery or any similar infectious disease in the community, the bacteria are deposited in the cracks and crevices of the leaves of cabbages, celery, lettuce and such vegetables, and if they are eaten uncooked the disease is spread broadcast. Hence, in the Orient sensible people always eat their vegetables cooked, but it is to be confessed that a stroll through a Japanese garden generally destroys all desire for oriental vegetables in any shape. Boiled feces may be harmless, but they are not an esthetic condiment.

For these reasons the quarantine authorities in Manila forbade the importation of vegetables or any moist foods from cholera-infected ports, but one ship captain is said to have disobeyed orders and thrown Chinese vegetables overboard. They are reported to have been picked up on shore. What we certainly know is, that along this shore the first cases occurred in an epidemic which destroyed lives estimated variously at from 150,000 to a half million.

Though infected water is the chief means of spreading the disease locally from man to man in an infected territory, it is so rarely the means of carrying the disease into an uninfected area that it can be dismissed. I do not know of a single instance in the large area from which I received reports. Of course it is possible, as where boats take infected water into their tanks and spread the disease at the terminal port, but in that case there is sure to be an extensive epidemic on the boat, which will lead to prompt measures. This is due to the fact that the vibrio perishes in so short a time outside of the host. Experimentally, it has been shown to die in distilled water in 24 hours, in water of canals in one to four days—Koch says in 36 hours. In sterilized milk it lives 10 days; in unsterilized milk, 1 to 2 days; in decoction of tea, 1/200, 8 days; in coffee, 2 hours; beer, 3 hours; acid wine, ¼ hour.

The subject of the prevention of the spread of the infection into a clean territory is foreign to this paper, but it is appropriate to remark that, theoretically, it seems a very simple matter. If a quarantine can be organized on sufficiently rigid lines, so as to stop every traveler at the point of destination for five days, every infected person could be discovered and his discharges disinfected until he recovers. Unfortunately, the spirilla remain in a convalescent many weeks or even months —they have been found seven weeks after all symptoms had disappeared. To keep him under control, then, is not as simple as it appears. Long after he is apparently well he may be a dangerous source of infection and nothing is safe except returning him to the territory whence he came. The quarantine itself is not always practicable, because it is easy to break through the lines, and this happened so often as to raise a suspicion that it was a useless bother and expense. Indeed, there are some who claim that as a land quarantine is sure to be inefficient and the infection spread in spite of our efforts, it is not wise to attempt any restrictive measures of the sort. This is rather fallacious reasoning and if we apply it to all human endeavors we would never attempt anything, for our efforts are rarely wholly successful. A quarantine does restrict the spread of cholera and to that extent it is an essential measure, for it lessens the number of new foci and restricts the number of deaths while we are waiting for the spirillum to lose its vitality, and this is a matter of only a few months. A marine quarantine is, of course, an entirely different matter and can be more efficient except in the matter of the retention of convalescents in the long period in which they can spread the infection.

---

[*] Read in the Section on Hygiene and Sanitary Science of the American Medical Association, at the Fifty-sixth Annual Session, July, 1905.

It is certain that if on the discovery of the first cases in Manila that part of the city had been surrounded with guards, with orders to shoot any one escaping, and this severe quarantine had been continued for two months after the last case. the subsequent epidemic in the Philippines would have been prevented, but it is also evident that such measures would never be tolerated by public sentiment.

Commerce in dried merchandise need not be interrupted in the least, but moist foods from an infected territory must, of course, be wholly excluded. Particularly in the Orient is this necessary, where, as before explained, the farmers are so filthy. The outcry against quarantine invariably raised by commercial bodies interferes with its efficiency. Indeed, there is much to be said on the side of the merchants. Interference with trade is a very serious matter and may in the end cause poverty, privation, sickness and eventually lay the foundation for more deaths than the unrestricted spread of the cholera. Oriental communities are dreadfully overcrowded, and a large death rate is normal and necessary. Many must die, for the food supply is always short, and there is much to be said in favor of the present attitude of the British sanitarians in India who have in sheer hopelessness given up the task of preventing the spread of plague and such epidemics and are allowing the natives to kill themselves in the way which pleases them most. It seems brutal, but a careful investigation of the whole question generally convinces one that in dealing with Orientals *laisse faire* is more often the best motto than we are willing to confess.

We now come to the most important side of cholera—its spread from man to man, after the spirillum has been introduced into a new territory. Here we have very definite data and we can lay down an invariable law, that without an infection of the water supply an extensive epidemic is impossible. Sporadic cases can occur in a city from infected foods and there may be little local outbursts here and there. as where a well has been infected, but unless the spirillum enters the water supplied to a great population, that population is comparatively safe. The first thing done in Manila was to guard the water supply by military forces, and to this wise measure we can surely attribute the salvation of that city from a terrible disaster.

To be sure, Manila had some thousands of cases, a few no doubt due to wells here and there into which surface discharges drained, but the vast majority were due to the extremely filthy habits of the people in their food supplies. It is said that there are 50,000 people in that city who feed from the little restaurants which exist by hundreds and sell various kinds of soups, stews and other cooked foods. A prospective purchaser will run her hands into the mixture and if it does not suit her will pass on to the next merchant. If she has just helped to attend a cholera patient hidden away in her home, she inoculates the stew from her finger nails, and the mixture, being a fine culture medium, is soon swarming with spirilla. In this manner and from equally filthy household habits almost all of the Manila cases can be attributed. But they were mostly sporadic cases, here one and there one, probably only one member of a family. Now and then a single pupil in a boarding scohol would be stricken, and investigation would bring to light the fact that she had received food from the outside, say some confectionery or a salad. Flies undoubtedly carried the infection from patients' discharges to exposed food supplies and started cultures this way, but this was of minor importance in the presence of the far more numerous ways of carrying it on the hands of filthy natives.

In the provinces we no doubt had many similar cases, but the bad epidemics of towns were invariably due to infected waters. The streams in the Philippines are the life of the country, and houses are built on the banks or overhanging them, so that the stream acts as a water supply and sewer for every one. It naturally followed that, as soon as a case occurred, the discharges entered the water and there was a general epidemic in the population living further down stream. Where the stream was large and there was a chance that one might drink some of the water without happening to take in a spirillum, the epidemic was not extensive, but where the stream was small and more crowded with spirilla the results were dreadful. In one town of this latter sort, the reports showed that over 25 per cent. of the inhabitants died within two or three weeks of the first case. In prior epidemics towns have been totally wiped out. Where there were many wells in addition to the stream, it was natural that some of them would escape infection and the users of that water escape. In one town, a famous spring supplied part of the people who were quite free of the disease which nearly decimated those using the river, and in those towns where the rich had well-protected cisterns for rain water these families were quite immune, excepting the sporadic cases infected elsewhere or from infected foods.

As before explained, the life of the spirillum in water is quite short. Reports from India show that infected wells and tanks are safe after three weeks, though we made no similar investigations in the Philippines. This fact gives the rational basis for the management of an epidemic. Of course, we must search for and destroy infected foods and prevent the sale of certain vegeta like cabbage, which can harbor the germs, though of the fruits and vegetables forbidden in the Man demic were absolutely harmless. Mangoes, for are not known to carry the infection. Banana ably safe, though there was a rumor at one t circulation of fluids in the plant was so rap

could be carried up from the roots to the interior of the fruit, but it is safe to say that this is merely an illustration of the wild thoughts possible in the nervous tension of an epidemic.

The sterilization of the urine and feces of cholera patients is also of importance to prevent the bacilli being washed into any water supply. Deep burial or sterilization by heat are impracticable, and dependence must be placed on one of the methods of chemical sterilization useful in typhoid. Experimentally it is found that the cholera vibrios are killed in a few minutes by weak solutions of carbolic acid or corrosive sublimate, and by mineral acid, 1/10000, in a few seconds, but for excreta it is thought that milk of lime is the best, in the proportion of 1 part lime to 40 of water.

We must search for the sick, who are invariably concealed to escape quarantine, and we must isolate them to prevent them from fouling a water supply, and finally we must close up for several weeks all wells, tanks and cisterns known to be infected. The British sanitarians are wedded to the plan of disinfecting such cholera wells by adding 2 to 4 ounces of permanganate of potash, in which solution the spirilli promptly perish. The permanganate is said to destroy all dead organic matter and thus to sterilize the water by depriving the spirilli of food so that they die of starvation. To be effective there must be a faint pink tinge in the water the day after the permanganate is used. Foul wells which destroy the color at once should be pumped out, if possible, and cleaned. In the absence of permanganate, alum has the next best reputation, 4 to 8 ounces to a well, but it is a clarifier rather than a disinfectant and carries down the bacteria in the coagula it forms. Finally, lime, 40 to 50 pounds to a well has been used, but it is not a safe means, as we have no data that it destroys the spirilli, whereas the permanganate has been repeatedly known to stop an Indian epidemic in 3 days after it was added to every well in town. Of course, we run the risk of being accused of poisoning the wells, but we will be accused of this, anyhow, so it makes no difference.

The main reliance must be placed on boiled water for all purposes. The more completely we could enforce this measure the more successful was the management of an epidemic. It was quite possible to do this among soldiers, though they were apt to be careless until one or two in a company died through disobedience, but among the natives any such plan was hopelessly impractical, as a rule. They could not possibly understand why it was necessary to boil the water, and have been known to take boiled water into the house as a fetish of some sort and *then drink what they pleased*. Hence, among an Oriental population, prevention of spread of the infection is not possible, never has been and never will be. The white man must do the best he can for the natives, but look out for himself. The permanganate method is the best in such circumstances, but where the natives use an infected stream we are helpless, and the natives will die until the stream is cleaned out by a heavy storm. Time and time again in the Philippines have local epidemics ceased after a long heavy rain. It not only washes out the stream bed, but each native collects rainwater to save
dead
shortes trouble of carriage, and there is less use of the in-
tion to wells. On the other hand, we have seen local epi-
brings the increase with the rains where the surface filth
desperately been washed into wells which were previously

to patent sterilizers, such as the Forbes- ·pinions are divided. This particular one contrivance for boiling water and then to save fuel using this hot water to heat up the incoming stream. It boils the water only a few seconds, but when carefully tested in a laboratory by skilled bacteriologists and intelligent men it delivers a steady stream of sterile water. In the field in actual use it is rarely successful, and I have repeatedly seen it used *without heat at all*. It is an extremely dangerous contrivance. The same condemnation must be given to all forms of portable filters. If they work easily, they merely act as clarifiers, as the spirilli easily pass through such large pores. When they are efficient they require considerable pressure which can only be obtained in permanent plants. The large permanent filters for public supplies have proved themselves efficient in filtering out cholera spirilli and need no further comment. The use of copper sulphate in minute doses or of copper foil is worthy of trial in wells and cisterns, for it may be of extreme value in the absence of the permanganate of potash.

If it is really true that a strip of copper foil 3 inches square in the water bottles will destroy intestinal parasites accidentally present, we have a most valuable discovery for tropical residents who can rarely depend on filthy natives. Indeed, it is suspected that here and there dysentery may have been due to unboiled infected water introduced by servants after they had stolen the water carefully sterilized by the master himself. The matter deserves the greatest attention in our laboratories. Acidulated water is no doubt efficacious if cholera is present, as the bacilli are destroyed by mineral acids, but it is unpleasant and will not be used except under compulsion, and the copper foil treatment is, therefore, an advantage if it proves to be germicidal. The use of acid in wells is apt to be resented by the natives much more than the permanganate and is probably less efficacious.

The extreme case of personal prophylaxis is comforting at least. We lived for a year in the midst of this disease, sometimes seeing the natives die all around us, and in our houses, even in our kitchens, but if we were sure to drink only boiled water, or bottled fluids known to be sterile, and ate only cooked or canned foods from scalded dishes, there was not the slightest danger. The patient himself is as harmless as one with typhoid, and if his discharges are sterilized or buried he never transmits the disease to his nurses. Cases could be cared for in the main hospital or, indeed, anywhere, for isolation was wholly unnecessary. In the first excitement of the epidemic, rather hysterical orders were sent out to cremate the bodies of the dead and burn down their houses, but this was all unnecessary. The buried corpse was harmless, for the spirilli perished at once. One military campaign was made in Mindanao in territory where every stream was infected and the natives were dying in large numbers, but not a soldier was taken sick. If soldiers violated orders and drank from streams, the results were dreadful. In another campaign the commanding officer of one company and eight or ten of the men died from this carelessness.

The spirillum is such a pure parasite that it will soon die even in India, so that it is kept alive by constantly passing through new hosts in those regions where it is endemic. Outside of India it loses vitality in its excursions from host to host, so that in the course of time it is too enfeebled to infect a new host, and the disease dies out. In any one locality its virulence diminished in a few months or even weeks, so that toward the end of a local epidemic many patients recovered and the physicians in attendance built up fine reputations for curing their cases. My own experience and the supervision of very many different methods of treatment led me to the conclusion that there was nothing to be done for the patient, except make him as comfortable as possible. Morphin, hot applications and massage for the cramps, with strychnin and other heart stimulants later, were about all that could be done. Remedies by the stomach were only rejected, and saline injections, either intravenous or hypodermic, only passed into the intestines within a few minutes and drained off more blood serum. If the patient lived through the acute stage, he could be saved by skillful management of his food and stimulants, but the treatment of the acute stage is hopeless. It is purely a matter of the patient's resistance and the virulence of the particular culture of spirillum he has swallowed.

* Read in the
American Medical
July, 1905.

Haffkine, in India, and Murata, in Japan, have apparently produced a certain degree of immunity by injecting the killed spirilli, and Strong, in Manila, has encouraging results with the fluid from which the killed spirilli have been filtered. Strong's filtrate causes a serum to form in man and animals which has high bactericidal and agglutinative power, though but slight antitoxic power. Work along these lines gives our only hope of future success.

Our main reliance, then, in cholera epidemics outside of India is to quarantine the infected area as rigidly as possible, protect water supplies, close up those known to be infected, use permanganate in the wells and cisterns, remove the sick to where they will be harmless, try to get the natives to use boiled water, prevent the sale and exposure of foods which are good culture media, and patiently wait until the spirilli have lost their virulence.

The above paper contains the conclusions to which we came as a result of the personal management of a severe and widespread epidemic, and it is also based on several score reports which came into my hands as chief surgeon of two of the brigades in the Philippines. As it would be meaningless and a waste of time to quote names, places, dates and statistics, these have been omitted, but it may be remarked that the official reports themselves are on file. It was requested that this paper would also include an account of the *Spirillum choleræ asiaticæ*, but we have discovered nothing new about this organism which is not already in the text-books.

We can conclude that we need never be afraid of a cholera epidemic in America, as sufficient is known to prevent it if we will not interfere with the sanitarians. One more Oriental plague has been removed from the list which has been the dread of the Occident, and once again we have a lesson that the people for their own protection had better give more authority to the sanitarians.

DISCUSSION.

Dr. Denslow Lewis, Chicago, stated that his experience with cholera is necessarily very limited, being confined to observations in Europe in 1892, at which time he visited the principal European cities as a special commissioner from the Health Department of Chicago and from the Illinois State Board of Health. Cholera broke out at Hamburg at that time and there were cases in Paris and a few in London. In Great Britain, the matter became of very serious importance on account of the isolated condition of that country, and Dr. Thorn-Thorn, now deceased, and Dr. Shirley Murphy of the health department of London were up in arms against the entrance of cholera into England. Great excitement prevailed, and fear was expressed, not only that the cholera might spread, but that commerce would be interfered with. Dr. Lewis noted at that time the great value of having an effective sanitary organization throughout a country. In place of quarantining the ships, which would have interfered most seriously with commerce, it was possible in discharging the passengers to have each one under surveillance, so that no matter to what little town in England, Ireland or Scotland he should go, there would be a health officer there who would keep track of him and isolate him in case he showed any suspicious symptoms. Dr. Lewis said that it would be well in this country if our sanitary measures could be centralized to some extent, so that such a system of surveillance in case of necessity might be possible. It is easily seen what very great value this system has under these conditions. Dr. Lewis recalled a conversation he once had with Commander Lucien Young, in which the latter informed him that when his ship was in an infected harbor, the exceptional health of his men was remarked on. The sailors of other ships became ill, and many of them died, but his sailors were well. He attributed this freedom from disease to the use of alcohol, which he recommended on that occasion, and Dr. Lewis asked Dr. Woodruff's opinion regarding this matter, because, if alcohol under these conditions is of value, it is an important fact for physicians to know, for the lives of many of our sailors may depend on their knowledge.

Dr. Woodruff said that with regard to quarantine at the port of entry, the British solution is the proper one for them. The existence of Great Britain depends on its trade, and any interruption of it, even for a short time, would be fatal. Two-thirds of the people get their food from America, and at times there is on hand, so it is said, only three or four weeks' supply, so that they would really suffer from want of food in case of an interruption of their traffic for more than that time. That is the reason why war between Britain and America is utterly impossible; the British would not permit it. Consequently, they must have some means of following up cases and of preventing interruption of trade, and their splendidly organized sanitary service allows them to do that; but there is no other place in the world that Dr. Woodruff knows of where it can be done. All other places would have to keep a ship under surveillance. If there were any sick, they would be isolated, but the others could not be turned loose until it was certain they were not infected. With regard to alcohol, he said that the evidence is conclusive that any irritation of the stomach from alcohol permits the bacillus to get through into the intestine. It seems as though a person on a spree who drinks infected water is very apt to have cholera; Dr. Woodruff has seen that occur a number of times among soldiers. The stomach is undoubtedly able to dispose of an enormous number of spirilli, and in an epidemic people must be drinking spirilli all the time, but as they are killed in a few minutes in any acid solution, even one to ten thousand, the stomach juices in good health will destroy them. A man is safe unless he drinks an exceedingly large number of the germs; but if a soldier is allowed to go on a spree or to acquire in other ways an acute gastritis, it alters the tone of the stomach and probably lowers the acidity of the juices. Dr. Woodruff found many cases of soldiers dying shortly after drinking large quantities of alcohol. There is no evidence that small quantities of alcohol do any harm, but he does not think that alcohol is beneficial except in the case of acid wines. The spirilli will not live on the cut surface of a lemon, for instance, and acid drinks of all kinds are beneficial. The majority of physicians agree that it is better not to be a total abstainer in the tropics, but they are not willing to go on record, because it is so revolutionary. The very foundation of our faith in tropical hygiene is total abstinence, but Dr. Woodruff is convinced from the statistics that he has gathered that a little stimulant with lunch and dinner, but at no other time, is a very good thing, though excessive drinking is exceedingly bad.

A Voice from the Tombs Warning Against Quacks.—There is said to be a monument in the graveyard at Hameln, in Germany, over the graves of two children who died in 1792, which bears the following inscription. It states that the children were sent to death "by a charlatan's hand—a warning to the entire land. Trust your life only in the hands of a sure physician; if you die then you will at least have done your duty."

> Wir sind durch eines Pfuschers Hand zu früh hierher geschicket.
> Zur Warnung für das ganze Land und den, der dies erblicket.
> Sein Leben traue jedermann nur sich're Aerzte Händen an;
> Geht er dann auch die Todesbahn, hat er doch seine Pflicht gethan.

could be carried up from the roots to the interior of the fruit, but it is safe to say that this is merely an illustration of the wild thoughts possible in the nervous tension of an epidemic.

The sterilization of the urine and feces of cholera patients is also of importance to prevent the bacilli being washed into any water supply. Deep burial or sterilization by heat are impracticable, and dependence must be placed on one of the methods of chemical sterilization useful in typhoid. Experimentally it is found that the cholera vibrios are killed in a few minutes by weak solutions of carbolic acid or corrosive sublimate, and by mineral acid, 1/10000, in a few seconds, but for excreta it is thought that milk of lime is the best, in the proportion of 1 part lime to 40 of water.

We must search for the sick, who are invariably concealed to escape quarantine, and we must isolate them to prevent them from fouling a water supply, and finally we must close up for several weeks all wells, tanks and cisterns known to be infected. IMMUNITY.

CHAPTER XXVII (Concluded).

TUBERCULOSIS.

Principles of Prophylaxis.

The essential principles in the prevention of tuberculosis consist of first, the early recognition of the disease, so that the patient may be properly treated and cured, if possible, with the result that a new center of contagion is avoided; second, the rendering of well-developed cases harmless by suitable isolation and proper disposal of infected excretions; third, the disinfection of the rooms, clothing, linen and surroundings of tuberculous patients. A fourth point, the prohibition of marriage among the tuberculous, is of great consequence, although we have little ground to hope for its realization on account of sociologic considerations. A fifth point, not yet fully established, is the possibility of universal vaccination against the disease.

In most cases the burden of early diagnosis falls on the family physician, and in addition to the usual clinical and bacteriologic methods of examination, the use of tuberculin is often of value when given as described below. That tuberculosis of the lungs and cervical lymph glands is curable in a large percentage of the cases when subjected to modern methods of hygienic or surgical treatment is now sufficiently well known. Aside from radical intervention, as practiced in surgical cases, the most important procedures are those of keeping the nutrition of the patient at the maximum and providing for a life in the fresh air and sun.

Disposal of Sputum.

The collection of infected sputum in properly constructed water-proof paper boxes, which, with their contents, should be burned daily, is the safest method of disposing of this material, and the most effective means of preventing infection of the patient's surroundings. Metallic, glass or earthenware sputum-cups containing 5 per cent. carbolic acid are serviceable, but the frequent cleansing to which they must be subjected is not without danger to others. When sputum is collected on a handkerchief the latter should be boiled within twelve hours and not allowed to dry; that the hands of the patient are likely to be contaminated from the handkerchief is evident. In coughing, the handkerchief should be held to the mouth to catch droplets of sputum and saliva which are expelled. The ordinances and rules which prohibit expectoration in street cars and public places should be enforced. When bacilli are discharged in the urine and feces or in the pus of tuberculous abscesses and sinuses, these secretions should be disinfected by suitable means (chlorid of lime). Healthy persons should come in contact with the tuberculous as little as possible, and the eating utensils of the latter should be used by no one else.

Disinfection.

The floor of a room which is inhabited by a tuberculous person should always be moistened before it is swept, in order to avoid stirring up the dust. After the death or removal of a patient, the entire surface of the room and all its contents should be thoroughly disinfected by appropriate means. The proper disinfection of the premises which were once occupied by a consumptive should be a legal requirement, just as similar procedures are demanded in the case of smallpox and some other contagious diseases.

The special hospital in which the indigent tuberculous may be properly cared for and isolated has been a powerful factor in causing the decrease of tuberculosis which has been noted in many countries. The removal of a patient to such an institution means the elimination of an infected focus from the community.

Susceptibility and Immunity.

Racial and Individual Variations.

Cold-blooded animals (fish, amphibians, reptiles), and most birds are not highly susceptible to tuberculosis, although special varieties of the bacillus cause the disease in certain of them under natural conditions. When tubercle bacilli are injected into the circulation of birds, they may remain in the blood and organs for months, producing little or no tissue change, although they retain their virulence for other animals (guinea-pig). No animal exceeds the guinea-pig in its susceptibility to this disease. Goats and sheep are fairly resistant, and the same is probably true of the horse, although its artificial infection is not difficult. That different races of a species may vary in their susceptibility is illustrated by the field mouse, which is highly susceptible, and the white mouse, which is relatively immune. Although similar variations may exist among different races of men, they are not readily demonstrated. The high susceptibility which appears to exist among certain races, as the negro, may be explained in part by unhygienic methods of living, in which safeguards against infection are not taken.

The discovery of healed or healing tuberculous foci in 70 to 90 per cent. of all autopsies, in contrast to the 15 to 20 per cent. of deaths from tuberculosis, shows that susceptibility and immunity are subject to marked individual variations. The ability of an individual to overcome a tuberculous infection is referred in a vague way to an unusual resistance on his part; his defensive powers are said to be strong. Although we remain to a large extent in the dark concerning these defensive powers, they seem to rest chiefly in the ability of the tissues to destroy the bacilli; that is, the resistance is antibacterial. Many bacilli may be destroyed by leucocytes or endothelial cells before they are able to cause tissue changes. It was stated previously that healing in many instances depends on isolation of the focus by epithelioid, lymphoid and plasma cells, and by connective tissue. On general grounds we may assume that a tissue reaction of this nature takes place with greater vigor and rapidity in a strong, healthy person than in one of lower vitality. Aside from the question of individual resistance, recovery or progressive infection may depend on the smaller or larger amount of bacilli which gained entrance to the body, as well as on their virulence. Experiments show that susceptible animals recover from minute doses, whereas they succumb to somewhat larger doses of bacilli.

Predisposing Influences.

Various external influences increase susceptibility and resistance. Tuberculosis is to no small degree a disease of the poor, who so frequently live in an undernourished condition, in crowded, dirty rooms, with little sunlight and fresh air. The disease is more common in the city than in the country, where an outdoor life is the rule. Alcoholism, diabetes, measles, scarlatina, whooping cough often, and influenza not infrequently, are precursors of tuberculosis. Conditions which favor anemia, as pulmonary stenosis (rare), predispose to pulmonary tuberculosis, whereas insufficiency of the left heart, accompanied by congestion of the lungs, is not often associated with the disease, although it has no influence in preventing infection in other organs. Tuberculosis is more frequent during the first two or three years of life, when children are so commonly confined, than from the third to the fifteenth years, when they live in the open air so largely. From the fifteenth year to middle life or later the disease increases in frequency because of greater exposure to infection. Physicians who are familiar with tuberculosis in Scandinavian countries and in America comment on the extent to which tuberculosis develops among Scandinavians after they come to this country.

"Hereditary Tendency."

Nothing is commoner than the occurrence of several successive cases of phthisis in the members of a family, and the expression, heard on all sides, that "tuberculosis is in the family," indicates the general belief that a family tendency may be transmitted from generation to generation. During recent years, however, closer analysis of the conditions has led many to doubt the existence or, at any rate, the importance of family tendency or inherited predisposition, and to refer the frequent occurrence of tuberculosis in a family to the greater exposure to infection which is occasioned by close contact with a pre-existing case. Cornet, who has made a close statistical study of tuberculosis, discredits entirely the hypothesis of hereditary predisposition, and Cornet and Meyer refer to the "*habitus phthisicus*," which we are disposed to look on as an objective evidence of hereditary tendency, as a result rather than a cause of pulmonary tuberculosis. It is fair to say that the development of tuberculosis in several members of a family is not *prima facia* evidence of the existence of a family predisposition for the disease. Where there are tubercle bacilli there is likely to be tuberculosis, and the occurrence of the infection in one furnishes the prerequisite, that is, bacilli, for the development of the disease in other members of the family. It is probable that the verdict of family tendency has often been pronounced erroneously. At the present time, however, we may not be justified in considering the subject a closed chapter.

Concerning Acquired Immunity.

It is the commonly accepted opinion that recovery from tuberculosis does not confer immunity to subsequent attacks.[1] Cornet and Meyer suggest as an explanation of this condition that the local lesion is so strictly isolated that a sufficient amount of toxin does not escape into the circulation to cause a general reaction, hence the formation of antitoxin or other antibodies is impossible. This explanation seems inadequate, however, when we remember the strong antitoxic immunity which develops in tetanus and diphtheria in spite of the localization of the bacteria. The results of artificial immunization, in which unlimited amounts of toxic material or bacilli may be injected without the formation of satisfactory antitoxins, seem to indicate that the toxic constituents of the tubercle bacillus lack the power of causing the formation of a strong antitoxin.

In opposition to the prevailing opinion, certain observers find ground for the belief that recovery from local tuberculosis of the lymph glands, skin or bones, actually does render the patients immune to pulmonary consumption (Maragliano and others). In early experiments Koch noted that when tubercle bacilli were injected subcutaneously into guinea-pigs which were suffering from general tuberculosis, the subcutaneous inoculation remained as a local infection and not infrequently healed after sloughing. The general infection would seem to have increased local resistance. Although other investigators failed to duplicate the observation of Koch, this result is said to have suggested to him the idea of active immunization as a cure for tuberculosis, a method subsequently practiced by treatment with the various tuberculins.

Active Immunization.

In the United States, Trudeau and de Schweinitz, and in Europe, Koch, Behring, Maragliano and Baumgarten, with their followers, have practiced assiduously the artificial immunization of animals with the tubercle bacillus or various preparation from the organism, with the hope of producing active immunity to the disease. Some of the procedures, especially those of Koch, have been transferred to man as curative meaures. In addition to active immunization of man, Maragliano especially has prepared an antituberculous serum, to which he assigns antitoxic and bactericidal properties, and which he and others claim to have used with good results in the treatment of tuberculosis. Marmorek also prepares an "antitoxic" serum.

The results of this work have shown the possibility of so increasing the resistance of various domestic animals (guinea-pig, sheep, rabbit, dog, calf, cow, etc.), that they withstand doses of bacilli which are invariably fatal for control animals. When the bacterial cells are used for immunization it is customary to begin treatment either with killed bacilli, or with living cultures which are naturally of low virulence, or the virulence of which has been lost by prolonged artificial cultivation. Relatively avirulent strains as those cultivated from fish, turtle or fowls, have been utilized for the first injections. As immunization progresses one of two processes may be followed: either the quantity injected may be increased gradually, as when killed or avirulent bacilli are used, or the immunization having been begun with avirulent living cultures those of higher virulence may be substituted gradually. In any case immunization is extremely difficult and slow, and many animals may be lost from cachexia or from tuberculosis which develops from hasty progression in dosage. The subcutaneous injection of intact cells has the disadvantage that local abscesses frequently develop, and to avoid this the intravenous injection of smaller doses has been practiced in some instances. For active immunization the "new tuberculin" of Koch, containing all the cellular constituents in a finely divided form has the advantages that it may be given subcutaneously without abscess formation and is absorbed with some rapidity. An animal or person immunized with TR is immune to all the constituents of the bacillus. The condition produced by active immunization is one of increased resistance rather than of absolute immunity; large doses of bacilli may cause infection. The nature of the new resistance is not satisfactorily established, although Maragliano refers to the formation of antitoxic and bactericidal substances.

Tuberculin in Diagnosis.

Inasmuch as tuberculin is used not only for diagnosis but also for curative purposes in man (active immunization), and since the principles of action are similar in both instances, the use of tuberculin may be considered at this point properly. From 0.5 to 1 c.c. of tuberculin may be injected into a normal guinea-pig without the production of local or general changes. When, however, 0.1 to 0.15 c.c. is given to a tuberculous guinea-pig the animal dies in from twenty-four to forty-eight hours. A healthy man likewise is not susceptible to moderate doses, but a tuberculous man is even more susceptible to the toxin than the tuberculous guinea-pig, since 0.001 c.c. often causes an intense reaction. E. Weigert classifies the disturbances which tuberculin may produce in the tuberculous as thermal, circulatory, respiratory, digestive, nervous and vasomotor, and secretory. Necrosis may be produced at the point of injection. In so far as the diagnostic use of tuberculin is concerned, we are interested chiefly in the thermal disturbances, which are accompanied by chills, malaise and muscular pains. Following injection of a suitable quantity, a period of incubation of from eight to fourteen hours follows, and at the end of this time the temperature rises progressively for two or more hours and may reach a maximum of from 40 to 41 C., and after remaining at this point for from two to six hours, recedes rapidly. In addition to this general reaction, the toxin causes congestion, redness and swelling at the site of the tuberculous lesion, i. e., the foci become surrounded by an inflammatory reaction. This is seen most readily in the tubercles of lupus vulgaris, and in the lungs is manifested clinically by an increase in the râles and expectoration which is caused by the exudation accompanying the inflammatory reaction.

For diagnostic purposes the technic of administration is as follows: It must first be assured that the patient has no continued fever by noting the temperature every two hours for several days. A quantity of 1 mg. of tuberculin is injected subcutaneously, this amount being obtained by suitable dilution of the original solution. If no temperature is produced by this amount, 5 or 10 mg. may be given in a second injection after an interval of two or three days. When the quantity is determined which causes a rise in temperature of one-half degree C. or more, the dose is to be repeated after the temperature produced by the first injection has subsided. Two such reactions should be considered necessary for positive diagnosis. One who after injection of 10 mg. on two different occasions gives no reaction is to be considered free from tuberculosis (Marx).

Limitations in Diagnostic Use of Tuberculin.

Experience has taught certain limitations to the diagnostic value of tuberculin: 1. The test can not be applied to febrile cases inasmuch as the pre-existing fever could not be separated from that which the tuberculin might produce. 2. Cases of advanced tuberculosis frequently fail to give the reaction. The tissues of such patients have become resistant to the poison. 3. It is said that tuberculin frequently causes a similar reaction in those suffering from leprosy, actinomycosis and syphilis. Cornet and Meyer suggest that the phenomenon as it is occurs in leprosy and actinomycosis, is to be considered in the nature of a "group reaction" in view of the close relationship of the tubercle bacillus to actinomyces and *Bacillus lepræ*. It does not always occur in syphilis, and in positive cases a latent tuberculosis may be responsible for the reaction. By a number of writers the facts just stated are taken to indicate that the reaction is not of specific character, and that it may often be obtained in the tuberculous by the injection of apparently indifferent substances as trypsin, peptone (albumose), sodium cinnimate and the "mycoproteins" of other bacteria provides additional support to this view. On the other hand, since relatively large amounts of these indifferent substances are required to produce the reaction, whereas minute amounts of tuberculin suffice, others hold that the specificity of the latter substance may be maintained.

---

[1] Similar conditions prevail in relation to pneumonia, influenza, erysipelas.

Early cases of tuberculosis react to tuberculin in the most typical manner. On account of the fact that latent or healing cases may respond to the test, its positive outcome gives no indication of the seriousness of the patient's condition, which is a practical question of some importance.

Danger (?) in Use of Tuberculin.

The fear that tuberculin, in producing an inflammatory reaction around tuberculous areas, might cause a dissemination of the bacilli, has acted strongly in preventing the use of the toxin for both diagnostic and therapeutic purposes. On *a priori* grounds, such an event would seem to be a possibility, for with the inflammation, the vessels surrounding the tubercles become congested, new leucocytes accumulate and there is an extravasation of fluid. Since during the subsidence of the inflammation a certain number of leucocytes may again leave the area and as the extravasated fluid returns to the circulation, bacilli may be carried away by the leucocytes or the fluid. Contrary to such reasoning, however, the observations of Koch and his followers in animal experiments and in the diagnostic and therapeutic use of tuberculin in man, lead them to say that tuberculin when properly administered never causes an aggravation or extension of the disease. Similar conclusions were reached by Trudeau, Baldwin and Kinghorn in animal experiments in which, "as in previous observations, a favorable absorptive influence was noted on the diseased focus." Bearing in mind the limitations mentioned above, and the possibility of the reaction being induced by leprosy, actinomycosis and syphilis (?), the statement of Osler may be quoted that "in obscure internal lesions, in joint cases and in suspected tuberculosis of the kidneys the use of tuberculin gives most valuable information."

Tuberculin Therapy.

The original unfavorable results which were obtained in the therapeutic administration of tuberculin are referred by Koch, Petruschky and others to improper selection of cases. Those in a febrile condition and those in whom destruction of tissue is advanced are not suited for the treatment, and in them little or nothing is to be hoped from administration of tuberculin. Its curative value is supposed to depend on the local inflammatory reaction which it causes around tuberculous foci, and perhaps also on the necrosis which Koch claims is caused in the tubercles themselves. It must be the object during the whole course of treatment to administer the toxin in such doses that a moderate or minimum local reaction occurs. Larger amounts which would cause febrile reactions and eventually render the patient resistant to tuberculin and thus preclude the local changes are to be avoided. It is customary to begin with 1/10 to 1/20 milligram and gradually to increase the amount injected. If fever is caused by a particular dose, larger amounts are not to be given until fever ceases to follow this dose. By the time a dosage of 50 milligrams is reached, which may require many months, the patient usually has lost the power of reacting and the injections are to be interrupted until he again becomes sensitive to the toxin (from three to six months), after which treatment should be resumed. Cure is recognized when the patient has lost permanently the power to react, his condition then being identical with the healthy man. Numerous German writers on the basis of practical experience assign an unquestionable curative power to tuberculin when administered as described. Its use has not extended widely.

The principles on which the action of tuberculin depend are hypothetical. Marmorek says that the fever and local changes are due to a special toxin (the true toxin), which the bacillus secretes under the stimulation of the tuberculin. Ehrlich supposes that cells adjacent to the tubercles have been injured moderately by the tuberculin which is produced *in situ*, and that as a consequence of this injury such cells are particularly susceptible to the additional tuberculin which is injected, and react to the stimulus by proliferation (Marx). In accordance with this conception the fever also in some obscure way is related to the local reaction. Investigations are needed to clear up this point.

Treatment with TR and "New Tuberculin."

In active immunization with TR, in which the solid constituents of the bacilli are injected rather than the toxic tuberculin, the cure is supposed to depend on the development of immune bodies rather than on local tissue changes. Koch published favorable results from its use, but reports from other sources were less satisfactory. The most recent preparation of Koch's, *Neutuberculin (Bazillenemulsion)*, consisting of finely powdered bacilli with all their toxic constituents, suspended in equal parts of glycerin and water, is used in a similar manner. Koch proposes to use the agglutinating power of the patient's serum as an index of the immunity caused by the injection. The formation of agglutinins perhaps indicates in a general way the ability of the patient to form antibodies, but from the well-known fact that the agglutinating power does not go hand in hand with the protective power of serum in relation to many infections, this method of estimating the degree of immunity does not rest on a good basis. The agglutination reaction is carried on with the emulsion which is used for immunization. Treatment in man is begun by the injection of 0.0025 mg. of solid substance and the amount is increased rapidly every day or two until a reaction occurs with a temperature of from 1.5 to 2 C. After a pause of a week the injections are begun again and eventually a dose of 20 mg. may be given. During treatment the agglutinating power of the patient's serum is tested frequently, and if it is not sufficiently high intravenous injection of the fluid portion of the emulsion may be practiced. The agglutinating power may go as high as from 1 to 25 to 1 to 150, rarely 1 to 200 to 1 to 300.

With both TR and the last preparation animals may be successfully immunized against tuberculosis.

Serum of Maragliano.

Maragliano, after many years of experimentation and treatment of human tuberculosis, concludes: "1, that it is possible to produce a specific (serum) therapy for tuberculosis; 2, that it is possible to immunize the animal organism against tuberculosis as is done in other infectious diseases, and that there is good reason to hope for an antituberculous vaccination for man." He speaks in rather broad terms of the defensive powers of the body against tuberculosis and seeks the demonstration of such powers in properties of the serum. He recognizes bactericidal, antitoxic and agglutinating properties of the serum as normal defensive powers of the body, and says that these powers are increased as the result of immunization. The bactericidal power of the serum is determined by its ability to inhibit the growth of cultures of the tubercle bacillus; its antitoxic power by its ability to neutralize a test poison which is obtained from cultures by macerating them in hot water; and its agglutinating power is tested with the homogeneous cultures of Courmont and Arloing. For the immunization of animals a soluble toxin prepared by the filtration of young cultures, and also the intracellular toxins which are extracted by water from killed virulent bacilli, are injected. By using both substances, antitoxic and other antibodies are said to be formed.

The serum of immune animals (horse, calf and cow) is used by Maragliano in the treatment of human tuberculosis, and the unusual claim is made that the serum is effective not only because of its own properties, but because it causes the tissues to form additional antibodies. Without discussing this apparently paradoxical condition we may only note the very favorable reports, from Italian sources especially, which have followed the use of the serum. Concerning 2,899 collected cases Maragliano says: "These statistics show that out of more than 250 patients with circumscribed *non-febrile* tuberculosis 38 per cent. were cured and 49 per cent. were much improved; that out of 938 patients with circumscribed febrile tuberculosis 18 per cent. were cured and 54 per cent. were improved; that out of 665 patients with diffuse tuberculous bronchopneumonia without microbic associations (mixed infection) 14 per cent. were cured and 43 per cent. were improved. Out of 332 patients with diffuse tuberculous bronchopneumonia with associated microbic infection 9 per cent. were cured and 36 per cent .improved. Of 712 patients with cavities 6 per cent. were cured and 40 per cent. were improved. Of all these patients 2,396 were in a *febrile condition*. The fever disappeared in 1,111 cases, i. e., in 46 per cent." Maragliano insists on the best hygienic surroundings for his patients, and under these conditions additional statistics show that a larger percentage of recoveries takes place among those treated with serum than among those who depend on hygienic surroundings alone. It is claimed that the serum manifests its curative powers and causes an increase in specific antibodies when given *per os*.

Mixed Immunization and Vaccination.

Maragliano also advocates a method of mixed active and passive immunization in man, in which a cubic centimeter of serum is given subcutaneously every second day for twenty days; for a second period the same quantity of serum is given, but supplemented by increasing amounts of the toxic extract of bacilli; and for a third period the toxic extract is injected in increasing doses during from three to four months.

The same authority thinks it may be possible to vaccinate against tuberculosis by a single subcutaneous injection of a vaccine (killed bacilli?). He states that in both man and animals antibodies are formed in the serum following the vaccination, and that in animals their resistance to infection with living bacilli is increased. Marmorek asserts that killed tubercle bacilli which have been treated with his antitoxic serum are readily absorbed from the subcutaneous tissue, and proposes the use of such bacilli as a vaccine.

Serum of Marmorek.

As stated above, Marmorek discredits tuberculin as the specific toxin of the bacillus. His "true" toxin is prepared by growing young and virulent bacilli ("primitive" bacilli) in a medium which contains leucotoxic serum, liver extract, glycerin and bouillon. The leucotoxic serum is prepared by immunizing calves with the leucocytes of guinea-pigs. Theoretical considerations which we need not detail suggested the use of this medium. The cultures are filtered after a few days of growth and the formation of tuberculin is avoided as much as possible. The immunization of horses with this filtered toxin yields the antitoxic serum of Marmorek. Conflicting reports concerning its value are published from French sources. Schwartz announces the complete cure of a case of tuberculosis of the larynx, and another of virulent tuberculosis of the conjunctiva and cornea by the exclusive use of Marmorek's serum.

Immunization by Milk.

Both Maragliano and Behring affirm that the immunizing substances are excreted in the milk of cows which have been strongly immunized against tuberculosis, and both have suggested that the use of such milk by infants may render them more resistant to tuberculosis.

The agglutination reaction has been suggested by Courmont and Arloing and others as a means of diagnosis in tuberculosis. Others who criticise this idea affirm that agglutinins are not developed sufficiently in the tuberculous to render the test of value, and that the serum of normal man may be as highly agglutinating as that of the tuberculous. In view of the fact that the tubercle bacillus grows in coherent masses in ordinary cultures special manipulations are necessary to render it suitable for the agglutination reaction. Courmont and Arloing prepare a homogeneous culture by first growing the organism on a certain potato medium and then in glycerin bouillon, which is frequently shaken. The cells are said to be well isolated after this procedure. Koch uses the emulsion of powdered bacilli for the test. The serum of man or animals as a result of immunization may reach an agglutinating power of 1 to 2,000 exceptionally (Maragliano).

Clinical Reports

AN UNUSUAL CASE OF SUNSTROKE.

J. G. JONES, M.D.

VINCENNES, IND.

I report this case because of the extreme rarity of sunstroke in this region during the autumn months, when the temperature usually ranges in midday from 78 to 88 F. in the shade, and also to demonstrate the occasional excessive susceptibility to an attack of sunstroke by an individual who has previously been stricken.

Patient.—A well-developed girl of 11 years of age, always in good general health, had been suffering with slight headaches for a few days previous to the attack. She had until recently been an inmate of the County Orphan's Home, when she had been taken for trial by some country people with a view to adoption. Her parentage history was rather obscure.

History.—On Sept. 15, 1905, at 11 a. m., the patient was standing near a tree in a garden on the hillside only partially exposed to the solar rays, awaiting the return of her companion. This individual returned within two minutes after leaving the girl to find her fallen to the ground and unconscious. The girl was carried to a neighboring farm house, where I saw her within three-quarters of an hour after the attack.

Symptoms.—The patient was in a deep coma; rectal temperature, 107 F. The skin was dry and flushed; pulse, 133 a minute, full and bounding; respiration, 33, irregular and deep. Clonic spasm of abdominal and respiratory muscles was brought on by touching the patient; in the intervals the muscles relapsed into flaccidity. Urine examination was negative. The eyes were suffused and staring. The pupils were widely dilated and remained in that condition for an hour, after which they contracted down to pin-point size, gradually reaching normal within another half-hour. In short, the classical symptoms of sunstroke of the hyperpyrexial form were present.

History of Previous Attack.—On inquiry, I found the history of a previous attack of unconsciousness while at the Orphan's Home during the summer of 1904, but could get no information as to what the diagnosis had been, yet, from the description given, I am sure it was a sunstroke. I excluded, with fair satisfaction, all the causes of coma, except sunstroke, and even with this negative diagnosis added to so classical an array of positive symptoms I found it difficult to accept that diagnosis, for the day was pleasantly cool, with a temperature of only 85 F. in the city at noon.

Treatment.—The treatment was very simple. The child was kept for several hours in a cold pack, with an ice bag at the head. Frequently changed cloths rung out in cold water were applied over the abdomen and precordial region, with an occasional rectal injection of cold water. Consciousness returned two hours after the attack, accompanied by some nausea. The temperature returned to normal by lysis within 24 hours, with no remission. There was complete recovery from the prostration in three days.

Remarks.—Some authorities speak of the pupils being contracted in sunstroke and consider this one of the diagnostic points, but it is my experience that they are nearly always first dilated for from 20 to 60 minutes and then contract to "pin point," where they remain for a variable period.

RUPTURE OF INTESTINES BY KICK OF A HORSE.

W. A. JOLLEY, M.D.

BOULDER, COLO.

History.—A. W., a stout farm hand, was kicked in the abdomen by a heavy horse at 12 m. He was thrown some distance by the blow, falling on his shoulder, and lay unconscious for several minutes. He vomited once, but presented no signs of shock. The abdomen showed only a small bruise and was not very painful, for 1/16 grain of morphin relieved the pain. He rested easily and complained more of the pain in his shoulder than of that in his abdomen, until 7 p. m., thirty hours after the accident, when he began to vomit and to present evidences of shock which rapidly increased. He died at 11 a. m., forty-seven hours after being injured.

Autopsy.—No external signs of injury. Internally, a general peritonitis from a transverse laceration of the small intestine about eighteen inches from the stomach. The laceration was one third of the circumference of the intestine.

I report the above case, as it illustrates that a very severe injury of the intestines may be present without giving any evidences until too late for surgical aid.

this view. On the other hand, since relatively large amounts of these indifferent substances are required to produce the reaction, whereas minute amounts of tuberculin suffice, others hold that the specificity of the latter substance may be maintained.

Early cases of tuberculosis react to tuberculin in the most typical manner. On account of the fact that latent or healing cases may respond to the test, its positive outcome gives no indication of the seriousness of the patient's condition, which is a practical question of some importance.

Danger (?) in Use of Tuberculin.

The fear that tuberculin, in producing an inflammatory reaction around tuberculous areas, might cause a dissemination of the bacilli, has acted strongly in preventing the use of the toxin for both diagnostic and therapeutic purposes. On *a priori* grounds, such an event would seem to be a possibility, for with the inflammation, the vessels surrounding the tubercles become congested, new leucocytes accumulate and there is an extravasation of fluid. Since during the subsidence of the inflammation a certain number of leucocytes may again leave the area and as the extravasated fluid returns to the circulation, bacilli may be carried away by the leucocytes or the fluid. Contrary to such reasoning, however, the observations of Koch and his followers in animal experiments and in the diagnostic and therapeutic use of tuberculin in man, lead them to say that tuberculin when properly administered never causes an aggravation or extension of the disease. Similar conclusions were reached by Trudeau, Baldwin and Kinghorn in animal experiments in which, "as in previous observations, a favorable absorptive influence was noted on the diseased focus." Bearing in mind the limitations mentioned above, and the possibility of the reaction being induced by leprosy, actinomycosis and syphilis (?), the statement of Osler may be quoted that "in obscure internal lesions, in joint cases and in suspected tuberculosis of the kidneys the use of tuberculin gives most valuable information."

Tuberculin Therapy.

The original unfavorable results which were obtained in the therapeutic administration of tuberculin are referred by Koch, Petruschky and others to improper selection of cases. Those in a febrile condition and those in whom destruction of tissue is advanced are not suited for the treatment, and in them little or nothing is to be hoped from administration of tuberculin. Its curative value is supposed to depend on the local inflammatory reaction which it causes around tuberculous foci, and perhaps also on the necrosis which Koch claims is caused in the tubercles themselves. It must be the object during the whole course of treatment to administer the toxin in such doses that a moderate or minimum local reaction occurs. Larger amounts which would cause febrile reactions and eventually render the patient resistant to tuberculin and thus preclude the local changes are to be avoided. It is customary to begin with 1/10 to 1/20 milligram and gradually to increase the amount injected. If fever is caused by a particular dose, larger amounts are not to be given until fever ceases to follow this dose. By the time a dosage of 50 milligrams is reached, which may require many months, the patient usually has lost the power of reacting and the injections are to be interrupted until he again becomes sensitive to the toxin (from three to six months), after which treatment should be resumed. Cure is recognized when the patient has lost permanently the power to react, his condition then being identical with the healthy man. Numerous German writers on the basis of practical experience assign an unquestionable curative power to tuberculin when administered as described. Its use has not extended widely.

The principles on which the action of tuberculin depend are hypothetical. Marmorek says that the fever and local changes are due to a special toxin (the true toxin), which the bacillus secretes under the stimulation of the tuberculin. Ehrlich supposes that cells adjacent to the tubercles have been injured moderately by the tuberculin which is produced *in situ*, and that as a consequence of this injury such cells are particularly susceptible to the additional tuberculin which is injected, and react to the stimulus by proliferation (Marx). In accordance with this conception the fever also in some obscure way is related to the local reaction. Investigations are needed to clear up this point.

Treatment with TR and "New Tuberculin."

In active immunization with TR, in which the solid constituents of the bacilli are injected rather than the toxic tuberculin, the cure is supposed to depend on the development of immune bodies rather than on local tissue changes. Koch published favorable results from its use, but reports from other sources were less satisfactory. The most recent preparation of Koch's, *Neutuberculin (Bazillenemulsion)*, consisting of finely powdered bacilli with all their toxic constituents, suspended in equal parts of glycerin and water, is used in a similar manner. Koch proposes to use the agglutinating power of the patient's serum as an index of the immunity caused by the injection. The formation of agglutinins perhaps indicates in a general way the ability of the patient to form antibodies, but from the well-known fact that the agglutinating power does not go hand in hand with the protective power of serum in relation to many infections, this method of estimating the degree of immunity does not rest on a good basis. The agglutination reaction is carried on with the emulsion which is used for immunization. Treatment in man is begun by the injection of 0.0025 mg. of solid substance and the amount is increased rapidly every day or two until a reaction occurs with a temperature of from 1.5 to 2 C. After a pause of a week the injections are begun again and eventually a dose of 20 mg. may be given. During treatment the agglutinating power of the patient's serum is tested frequently, and if it is not sufficiently high intravenous injection of the fluid portion of the emulsion may be practiced. The agglutinating power may go as high as from 1 to 25 to 1 to 150, rarely 1 to 200 to 1 to 300.

With both TR and the last preparation animals may be successfully immunized against tuberculosis.

Serum of Maragliano.

Maragliano, after many years of experimentation and treatment of human tuberculosis, concludes: "1, that it is possible to produce a specific (serum) therapy for tuberculosis; 2, that it is possible to immunize the animal organism against tuberculosis as is done in other infectious diseases, and that there is good reason to hope for an antituberculous vaccination for man." He speaks in rather broad terms of the defensive powers of the body against tuberculosis and seeks the demonstration of such powers in properties of the serum. He recognizes bactericidal, antitoxic and agglutinating properties of the serum as normal defensive powers of the body, and says that these powers are increased as the result of immunization. The bactericidal power of the serum is determined by its ability to inhibit the growth of cultures of the tubercle bacillus; its antitoxic power by its ability to neutralize a test poison which is obtained from cultures by macerating them in hot water; and its agglutinating power is tested with the homogeneous cultures of Courmont and Arloing. For the immunization of animals a soluble toxin prepared by the filtration of young cultures, and also the intracellular toxins which are extracted by water from killed virulent bacilli, are injected. By using both substances, antitoxic and other antibodies are said to be formed.

The serum of immune animals (horse, calf and cow) is used by Maragliano in the treatment of human tuberculosis, and the unusual claim is made that the serum is effective not only because of its own properties, but because it causes the tissues to form additional antibodies. Without discussing this apparently paradoxical condition we may only note the very favorable reports, from Italian sources especially, which have followed the use of the serum. Concerning 2,899 collected cases Maragliano says: "These statistics show that out of more than 250 patients with circumscribed non-febrile tuberculosis 38 per cent. were cured and 49 per cent. were much improved; that out of 938 patients with circumscribed febrile tuberculosis 18 per cent. were cured and 54 per cent. were improved; that out of 665 patients with diffuse tuberculous bronchopneumonia without microbic associations (mixed infection) 14 per cent. were cured and 43 per cent. were improved. Out of 332 patients with diffuse tuberculous bronchopneumonia with associated microbic infection 9 per cent. were cured and 36 per cent .improved. Of 712 patients with cavities 6 per cent. were cured and 40 per cent. were improved. Of all these patients 2,396 were in a febrile condition. The fever disappeared in 1,111 cases, i. e., in 46 per cent." Maragliano insists on the best hygienic surroundings for his patients, and under these conditions additional statistics show that a larger percentage of recoveries takes place among those treated with serum than among those who depend on hygienic surroundings alone. It is claimed that the serum manifests its curative powers and causes an increase in specific antibodies when given *per os*.

Mixed Immunization and Vaccination.

Maragliano also advocates a method of mixed active and passive immunization in man, in which a cubic centimeter of serum is given subcutaneously every second day for twenty days; for a second period the same quantity of serum is given, but supplemented by increasing amounts of the toxic extract of bacilli; and for a third period the toxic extract is injected in increasing doses during from three to four months.

The same authority thinks it may be possible to vaccinate against tuberculosis by a single subcutaneous injection of a vaccine (killed bacilli?). He states that in both man and animals antibodies are formed in the serum following the vaccination, and that in animals their resistance to infection with living bacilli is increased. Marmorek asserts that killed tubercle bacilli which have been treated with his antitoxic serum are readily absorbed from the subcutaneous tissue, and proposes the use of such bacilli as a vaccine.

Serum of Marmorek.

As stated above, Marmorek discredits tuberculin as the specific toxin of the bacillus. His "true" toxin is prepared by growing young and virulent bacilli ("primitive" bacilli) in a medium which contains leucotoxic serum, liver extract, glycerin and bouillon. The leucotoxic serum is prepared by immunizing calves with the leucocytes of guinea-pigs. Theoretical considerations which we need not detail suggested the use of this medium. The cultures are filtered after a few days of growth and the formation of tuberculin is avoided as much as possible. The immunization of horses with this filtered toxin yields the antitoxic serum of Marmorek. Conflicting reports concerning its value are published from French sources. Schwartz announces the complete cure of a case of tuberculosis of the larynx, and another of virulent tuberculosis of the conjunctiva and cornea by the exclusive use of Marmorek's serum.

Immunization by Milk.

Both Maragliano and Behring affirm that the immunizing substances are excreted in the milk of cows which have been strongly immunized against tuberculosis, and both have suggested that the use of such milk by infants may render them more resistant to tuberculosis.

The agglutination reaction has been suggested by Courmont and Arloing and others as a means of diagnosis in tuberculosis. Others who criticise this idea affirm that agglutinins are not developed sufficiently in the tuberculous to render the test of value, and that the serum of normal man may be as highly agglutinating as that of the tuberculous. In view of the fact that the tubercle bacillus grows in coherent masses in ordinary cultures special manipulations are necessary to render it suitable for the agglutination reaction. Courmont and Arloing prepare a homogeneous culture by first growing the organism on a certain potato medium and then in glycerin bouillon, which is frequently shaken. The cells are said to be well isolated after this procedure. Koch uses the emulsion of powdered bacilli for the test. The serum of man or animals as a result of immunization may reach an agglutinating power of 1 to 2,000 exceptionally (Maragliano).

Clinical Reports

AN UNUSUAL CASE OF SUNSTROKE.

J. G. JONES, M.D.

VINCENNES, IND.

I report this case because of the extreme rarity of sunstroke in this region during the autumn months, when the temperature usually ranges in midday from 78 to 88 F. in the shade, and also to demonstrate the occasional excessive susceptibility to an attack of sunstroke by an individual who has previously been stricken.

Patient.—A well-developed girl of 11 years of age, always in good general health, had been suffering with slight headaches for a few days previous to the attack. She had until recently been an inmate of the County Orphan's Home, when she had been taken for trial by some country people with a view to adoption. Her parentage history was rather obscure.

History.—On Sept. 15, 1905, at 11 a. m., the patient was standing near a tree in a garden on the hillside only partially exposed to the solar rays, awaiting the return of her companion. This individual returned within two minutes after leaving the girl to find her fallen to the ground and unconscious. The girl was carried to a neighboring farm house, where I saw her within three-quarters of an hour after the attack.

Symptoms.—The patient was in a deep coma; rectal temperature, 107 F. The skin was dry and flushed; pulse, 133 a minute, full and bounding; respiration, 33, irregular and deep. Clonic spasm of abdominal and respiratory muscles was brought on by touching the patient; in the intervals the muscles relapsed into flaccidity. Urine examination was negative. The eyes were suffused and staring. The pupils were widely dilated and remained in that condition for an hour, after which they contracted down to pin-point size, gradually reaching normal within another half-hour. In short, the classical symptoms of sunstroke of the hyperpyrexial form were present.

History of Previous Attack.—On inquiry, I found the history of a previous attack of unconsciousness while at the Orphan's Home during the summer of 1904, but could get no information as to what the diagnosis had been, yet, from the description given, I am sure it was a sunstroke. I excluded, with fair satisfaction, all the causes of coma, except sunstroke, and even with this negative diagnosis added to so classical an array of positive symptoms I found it difficult to accept that diagnosis, for the day was pleasantly cool, with a temperature of only 85 F. in the city at noon.

Treatment.—The treatment was very simple. The child was kept for several hours in a cold pack, with an ice bag at the head. Frequently changed cloths rung out in cold water were applied over the abdomen and precordial region, with an occasional rectal injection of cold water. Consciousness returned two hours after the attack, accompanied by some nausea. The temperature returned to normal by lysis within 24 hours, with no remission. There was complete recovery from the prostration in three days.

Remarks.—Some authorities speak of the pupils being contracted in sunstroke and consider this one of the diagnostic points, but it is my experience that they are nearly always first dilated for from 20 to 60 minutes and then contract to "pin point," where they remain for a variable period.

RUPTURE OF INTESTINES BY KICK OF A HORSE.

W. A. JOLLEY, M.D.

BOULDER, COLO.

History.—A. W., a stout farm hand, was kicked in the abdomen by a heavy horse at 12 *m.* He was thrown some distance by the blow, falling on his shoulder, and lay unconscious for several minutes. He vomited once, but presented no signs of shock. The abdomen showed only a small bruise and was not very painful, for 1/16 grain of morphin relieved the pain. He rested easily and complained more of the pain in his shoulder than of that in his abdomen, until 7 p. m., thirty hours after the accident, when he began to vomit and to present evidences of shock which rapidly increased. He died at 11 a. m., forty-seven hours after being injured.

Autopsy.—No external signs of injury. Internally, a general peritonitis from a transverse laceration of the small intestine about eighteen inches from the stomach. The laceration was one third of the circumference of the intestine.

I report the above case, as it illustrates that a very severe injury of the intestines may be present without giving any evidences until too late for surgical aid.

SUPPLEMENTARY COMMENTS ON THE RECENT WORK ON THE PNEUMOCOCCUS.

The studies on the pneumococcus under the auspices of the Medical Commission for the Investigation of the Acute Respiratory Diseases of the Department of Health of the City of New York[1] have resulted in valuable contributions to our knowledge of methods of identifying the pneumococcus, of differentiating it from the streptococcus and other simulating or closely related organisms and of its distribution and viability under various conditions.

The method adopted by the commission was, first, to secure the co-operation of twenty bacteriologists in various cities who made independent studies along the lines suggested, and, second, to establish a central laboratory or "clearing house," to which, ultimately, cultures from the various independent workers were sent for comparative study under a single group of observers. The birth of this species of organized "control" work will be hailed with delight by all who appreciate the susceptibility of an individual to error. And the wisdom of the plan is borne out by the results—many of the workers contributing valuable independent observations, while the central committee has served to minimize errors of identification and thus to increase the value of statistics to be ultimately based on the whole series of cases.

Bacteria were studied from the mouths of normal individuals, from pneumonic patients, from autopsies and from the sputum and exudates from pathologic cases other than pneumonias. Although the technic for identification varied considerably, the work is, in the main, supported by that of the central committee.
